9 **Abstract.** In this work, we investigated the influence of different types of soot aerosol on the counting efficiency
10 (CE) of instruments employed for the periodic technical inspection (PTI) of diesel vehicles. Such instruments
11 report particle number (PN) concentration. Combustion aerosols were generated by a prototype bigCAST, a
12 miniCAST 5201 BC, a miniCAST 6204 C and a miniature inverted soot generator (MISG). For comparison
13 purposes, diesel soot was generated by a Euro 5b diesel test vehicle with by-passed diesel particulate filter (DPF).
14 The size-dependent counting efficiency profile of six PN-PTI instruments was determined with each one of the
15 aforementioned test aerosols. The results showed that the type of soot aerosol affected the response of the PN-PTI
16 sensors in an individualised manner. Consequently, it was difficult to identify trends and draw conclusive results
17 about which laboratory-generated soot is the best proxy for diesel soot. Deviations in the counting efficiency
18 remained typically within 0.25 units when using laboratory-generated soot compared to Euro 5b diesel soot of
19 similar mobility diameter (~50-60 nm). Soot with a mobility diameter of ~100 nm generated by the MISG, the
20 lowest size we could achieve, resulted in most cases in similar counting efficiencies as that generated by the
21 different CAST generators at the same particle size, showing that MISG may be a satisfactory - and affordable -
22 option for PN-PTI verification; [however, further optimization will be needed for low-cost soot generators to](#)
23 [comply with European PN-PTI verification requirements.](#)

24 **1 Introduction**

25 Soot particles emitted by transport sources can have adverse health effects (Kheirbek et al., 2016; US-EPA, 2019;
26 WHO, 2021). To reduce particulate emissions, new procedures for the periodic technical inspection (PTI) of diesel
27 vehicles based on the measurement of particle number (PN) concentration have recently been established in
28 Switzerland, Germany, the Netherlands and Belgium, while other countries might follow in due time (EU, 2023;
29 Vasilatou et al., 2022). Portable instruments known as PN-PTI counters are used for measuring particle number
30 concentration (PNC) directly in the tailpipe of diesel vehicles equipped with a diesel particle filter (DPF)
31 (Kesselmeier and Staudt, 1999; Melas et al., 2021, 2022, 2023). When the DPF is intact, the emitted PNC is low
32 (typically up to a few thousand particles per cm³), whereas if the DPF is defect or tampered, PNC increases to
33 several hundred thousand particles per cm³ (Botero et al., 2023; Burtscher et al., 2019; Giechaskiel et al., 2022).
34 In terms of particle mass concentration, a functioning DPF can reduce particulate emissions by up to a factor of
35 150 (Ligterink, 2018) while in terms of particle number concentration a solid particle number trapping efficiency
36 of higher than 99 % has been reported in the literature (Frank, Adam et al., 2020). It has been shown that a small

37 fraction (about 10 %) of vehicles with defective DPF is responsible for up to 80-90 % of the total fleet emissions
38 (Burtscher et al., 2019; Kurniawan and Schmidt-Ott, 2006). The goal of PN-PTI procedures is to identify diesel
39 vehicles with compromised DPFs, thus ensuring that vehicles in operation maintain their performance as
40 guaranteed by type-approval, without excessive degradation, throughout their lifetime (EU, 2023).

41 Although the concept of PN-PTI is simple, its implementation in practice is not as straightforward. PTI procedures
42 are not fully harmonised and, as a result, the limit values for the emitted PNC, the technical specifications of the
43 PN-PTI counters and the test protocol for type-examination and verification are defined at a national level (Anon,
44 n.d.; AU-Richtlinie, n.d.; PTB, 2021; UVEK, 2023; VAMV, 2018; Vasilatou et al., 2022, 2023). Differences in
45 national legislations might lead to contradicting results, e.g. the same diesel vehicle might pass the PTI check in
46 one country but fail in another one. To ensure fair implementation of regulations across Europe and avoid
47 unnecessary costs which may occur for vehicle owners after a False Fail, the various PTI procedures must be
48 compared and the differences elucidated.

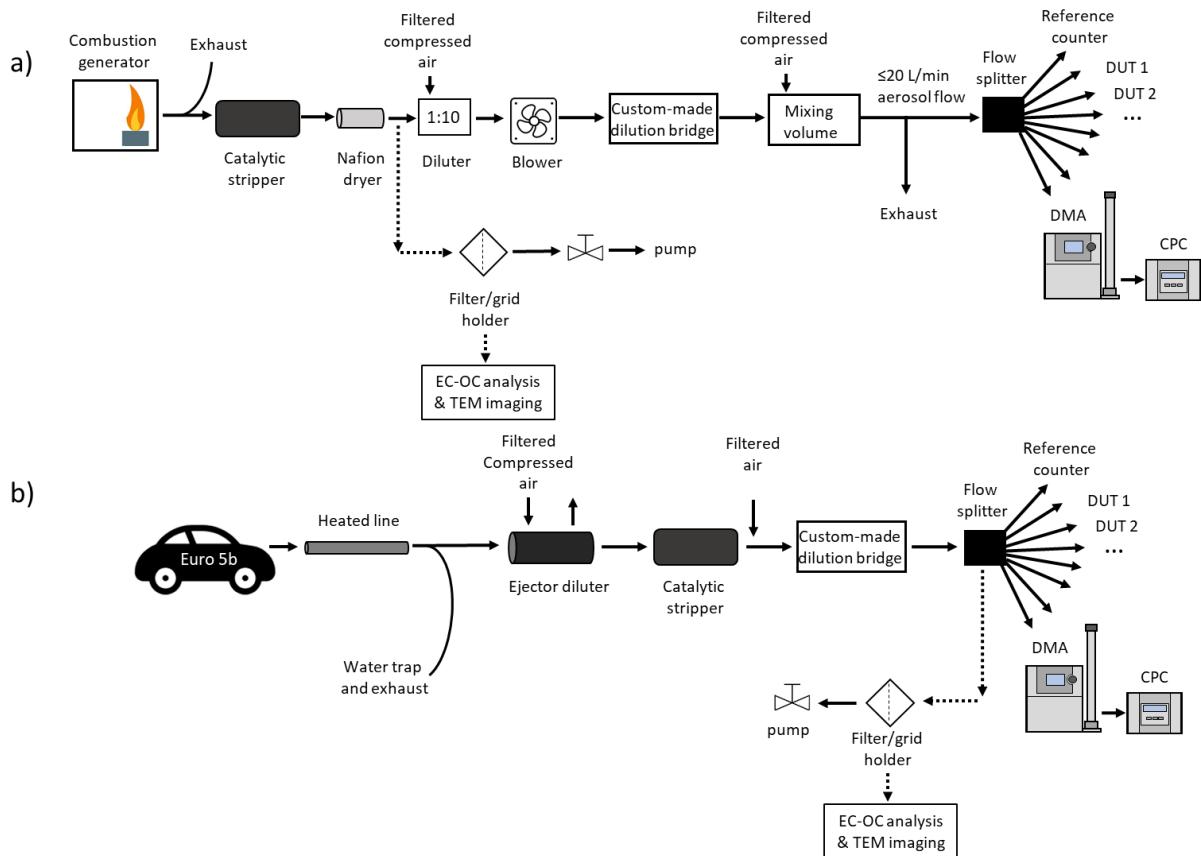

49 PN-PTI instruments go through a type-examination procedure which may differ in each country. Among several
50 tests, type-examination includes a counting efficiency and a linearity check typically performed with combustion
51 aerosols. During their lifetime, PN-PTI instruments are checked for their linearity with polydisperse particles
52 (typically with a GMD of 70 ± 20 nm). In our previous study (Vasilatou et al., 2023), we showed that the choice
53 of test aerosol during type-examination or verification of PN-PTI instruments significantly affects the performance
54 of instruments based on diffusion charging (DC). When sodium chloride (NaCl) or carbonaceous particles from
55 spark-discharge generators were used as test aerosols, the counting efficiency of the DC-based instruments
56 changed by up to a factor of two compared to that exhibited with diesel soot. The experiments clearly showed that
57 soot from laboratory-based combustion generators was the best proxy for soot emitted by diesel engines, however,
58 potential differences between the different combustion generators available on the market were not investigated.
59 In this study, we challenged six different DC-based PN-PTI instruments with polydisperse soot particles produced
60 by three different CAST generators (Jing AG, Switzerland), the miniature inverted soot generator (MISG,
61 Argonaut Scientific, Canada) and a Euro 5b diesel vehicle. The geometric mean diameter of the test aerosol was
62 in the range used for linearity checks of PN-PTI instruments as well as in typical size range emitted by diesel
63 engines. The scope of our study was to investigate possible differences that may arise when using different
64 combustion aerosol generators during the type-examination and verification of PN-PTI instruments as well as to
65 correlate with diesel engine emitted soot. We focused on DC-based instruments because we expect a larger impact
66 of the aerosol properties on their response compared to CPC-based ones (Vasilatou et al., 2023). The size-
67 dependent counting efficiency of the PN-PTI instruments was determined by using a condensation particle counter
68 (NPET 3795, TSI Inc., USA) as a reference instrument. We discuss the results in the context of the different
69 national legislations and make recommendations for the harmonisation of the various calibration and verification
70 procedures in the laboratory.

71 **2 Materials and methods**

72 During the first measurement campaign at METAS, the following laboratory-based diffusion or premixed flame
73 generators were used to produce test aerosols: a prototype bigCAST, a miniCAST 5201 BC (Ess et al., 2021b; Ess
74 and Vasilatou, 2019), a miniCAST 6204 C and the miniature inverted soot generator (MISG) (Giechaskiel and
75 Melas, 2022; Kazemimanesh et al., 2019; Moallemi et al., 2019; Senaratne et al., 2023). By varying the operation

76 points of the CAST generators, polydisperse aerosols with a geometric mean mobility diameter (GMD_{mob}) ranging
77 from 50 nm to 100 nm were generated, as summarised in Fig. S1. In the case of the MISG, particles with a GMD_{mob}
78 down to 100 nm were produced in a repeatable and stable manner using a mixture of dimethyl ether and propane
79 (Senaratne et al., 2023). This is in agreement with another study, where the modal diameter varied between 95 and
80 158 nm (Bischof et al., 2020).

81 The counting efficiency profiles (CE) of six DC-based PN-PTI counters, namely the AEM (TEN, the Netherlands),
82 HEPAc (developed by the University of Applied Sciences Northwestern Switzerland and distributed by Naneos
83 GmbH, Switzerland), DiTEST (AVL DiTEST, Austria), CAP3070 (Capelec, France), DX280 (Continental
84 Aftermarket & Services GmbH, Germany) and AIP PDC KG4 (referred to as Knestel hereafter, KNESTEL
85 Technologie & Elektronik GmbH, Germany) [were determined experimentally](#). The HEPAc, DiTEST, CAP3070
86 and DX280 had been type-approved at METAS according to the Swiss regulations (VAMV, 2018) whereas the
87 Knestel instrument had been type-approved according to the German regulation (AU-Richtlinie, n.d.). The
88 experimental setup at METAS is depicted in Fig. 1a. Soot produced by CAST-burners or the MISG was passed
89 through a catalytic stripper (Catalytic Instruments GmbH, Germany), a Nafion dryer (MD-700-12S-1, PERMA
90 PURE, U.S.A.), a VKL 10 diluter (Palas GmbH, Germany) and a custom-made dilution bridge, and was mixed
91 [and diluted with filtered air](#) in a 27-ml-volume chamber. [To deliver the aerosol into the mixing volume, a blower](#)
92 ([Micronel AG, Switzerland](#)) [was used](#). The aerosol was split with a custom-made 8-port flow splitter and delivered
93 simultaneously to the devices under test (DUT, in this case PN-PTI instrument) and the reference particle counter
94 (NPET 3795, TSI Inc., USA). [The splitter bias was determined according to the procedure specified in the ISO](#)
95 [27891 standard and was found to be within 1 % for particles with a \$GMD_{mob}\$ equal to or larger than 23 nm. In](#)
96 [addition, the length of the tubes from the flow splitter to the devices was adapted to the respective flow rate to](#)
97 [ensure equal diffusion losses.](#) The NPET was selected as reference instrument for two reasons; i) it could be used
98 in field measurements as it included a dilution system, a volatile particle remover and a particle counter, ii) during
99 type examination portable PN-PTI instruments are typically used as reference. NPET had been calibrated in a
100 traceable manner according to the ISO 27891 standard, and showed a CE of 0.77 ± 0.02 , 0.77 ± 0.01 , 0.80 ± 0.01
101 and 0.79 ± 0.02 at a GMD_{mob} of 50 nm, 70 nm, 80 nm and 100 nm, respectively and this counting efficiency was
102 taken into account during data analysis ([i.e. a calibration factor of 1.28 was applied to the concentrations reported](#)
103 [by the NPET](#)).

104

105 **Figure 1: a) Experimental setup for the verification of PN-PTI instruments in the laboratory. Four different combustion**
 106 **generators were used (see text for more details). DUT stands for device under test. Dashed arrows designate**
 107 **measurements which were performed separately, i.e. not in parallel with PN-PTI verification. b) Experimental setup as**
 108 **used for field measurements at JRC.**

109 Mobility size distributions were recorded simultaneously by a scanning mobility particle sizer (^{85}Kr source 3077A,
 110 DMA 3081 and butanol CPC 3776, TSI Inc., USA). To analyse the morphology of the soot particles, particles
 111 were sampled for 5 s with a flow rate of 1.2 L/min downstream the Nafion dryer, collected on copper-coated TEM
 112 (transmission electron microscopy) grids placed in a mini particle sampler (MPS, Ecomeasure, France) and
 113 analysed with a Spirit Transmission EM (Tecnai, FEI Company, USA). Soot particles were also sampled on QR-
 114 100 Advantec filters (Toyo Roshi Kaisha, Ltd. Japan, preheated at 500 °C for > 1 h) for durations of 15 – 30 min.
 115 Elemental carbon (EC) to total carbon (TC) mass fractions were measured with an OC/EC Model 5L analyser
 116 (Sunset Laboratory Inc., NL) by applying an extended EUSAAR-2 protocol (Ess et al., 2021b, 2021a).

117 In a second measurement campaign at JRC, the HEPaC, DiTEST, CAP3070 and DX280 counters were challenged
 118 with real diesel engine exhaust from a Euro 5b vehicle. Fig. 1b depicts the experimental setup at JRC. Soot from
 119 engine exhaust was passed through a water trap, a heated line (150 °C) to avoid water condensation, an ejector
 120 dilutor (DI-1000, Dekati, Finland), a catalytic stripper (Catalytic Instruments GmbH, Germany) to remove
 121 (semi)volatile organic matter, and was diluted to the required concentrations with a custom-made dilution bridge.
 122 It has been shown that the ejector dilutor does not affect the particle size distribution (Giechaskiel et al., 2009).
 123 PNC was recorded for several minutes, which allowed identifying long-time trends or drifts of the reported PNC.
 124 In addition, PNCs were averaged over a period of 1 min, thus the duration was similar to the duration of real PN-
 125 PTI tests which varies from 15 to 90 s. Mobility size distributions were measured by an SMPS, consisting of an
 126 ^{85}Kr source (3077A, TSI Inc., U.S.A.; purchased in 2021), a DMA 3081 and a CPC 3010 (TSI Inc., USA).

127 A Euro 5b vehicle with by-passed DPF was tested as real source of diesel soot. The vehicle generated size
128 distributions with a GMD_{mob} of $56.4 \text{ nm} \pm 0.7 \text{ nm}$. Diesel particles from the Euro 5b vehicle were collected on
129 TEM grids [and quartz filters](#) and analysed as described above.

130 [The fractal dimension \$D_f\$ of size-selected soot particles with a nominal \$GMD_{mob}\$ mobility diameter \$d_p\$ of 100 nm](#)
131 [was derived via image analysis of high-quality TEM-images using the FracLac feature of ImageJ 1.53e \(ImageJ,](#)
132 [National Institutes of Health, USA\). In a first step, the greyscale TEM-images were converted into binary images](#)
133 [utilizing the auto-convert function of FracLac. In a second step, the \$D_f\$ values were determined via the so-called](#)

136 [described in \(Tavakoli and Olfert, 2014\).](#)

137 3 Results

138 3.1 Aerosol properties

139 Particle number concentration measured by diffusion chargers depends on the average number of charges carried
140 by each particle (Fierz et al., 2011). Particle size and morphology have been shown to have an effect on the number
141 of charges carried by the particles and, thus, on the counting efficiency of diffusion charger based PN-PTI
142 instruments (see (Dhaniyala et al., 2011; Vasilatou et al., 2023) and references therein). Soot particles form
143 complex structures described by a fractal-like scaling law (Mandelbrot, 1982), and their mobility is influenced by
144 their morphology (described by the fractal dimension and fractal pre-factor) and the momentum-transfer regime
145 (Filippov et al., 2000; Melas et al., 2014; Sorensen, 2011). To characterise the soot particles produced by the
146 different aerosol generators, the following aerosol properties were determined: particle size distribution, EC/TC
147 ratio, primary particle size and fractal dimension. EC/TC ratio can also have an effect on the morphology of the
148 soot particles. Soot particles formed in premixed flames (i.e. high EC/TC) exhibit a loose agglomerate structure
149 where the primary particles are clearly distinguishable from one another, while soot generated in fuel-rich flames
150 (high OC/TC) has a more compact structure and the primary particles tend to merge with each other (see Fig. 3 in
151 (Ess et al., 2021b)). [OC stands for organic carbon.](#)

152
153 The properties of the soot aerosols are summarised in Table 1. Mobility size distributions [and TEM images](#) are
154 shown in Fig. S1 [and Fig. 2, respectively.](#)

* Uncertainties of the EC/TC mass fraction (downstream of the CS) are estimated to be in the range of 10-15 %.

Uncertainties due to the split point could not be quantified and were not taken into account.

** Expanded uncertainty ($k=2$, 95 % confidence interval) determined as the twofold standard deviation of d_{pp} of at least 20 primary particles of various mature soot particles divided by the square route of the number of measurements.

*** Expanded uncertainty ($k=2$, 95 % confidence interval) determined as the twofold standard deviation of three measurements.

† Taken from (Ess et al., 2021b).

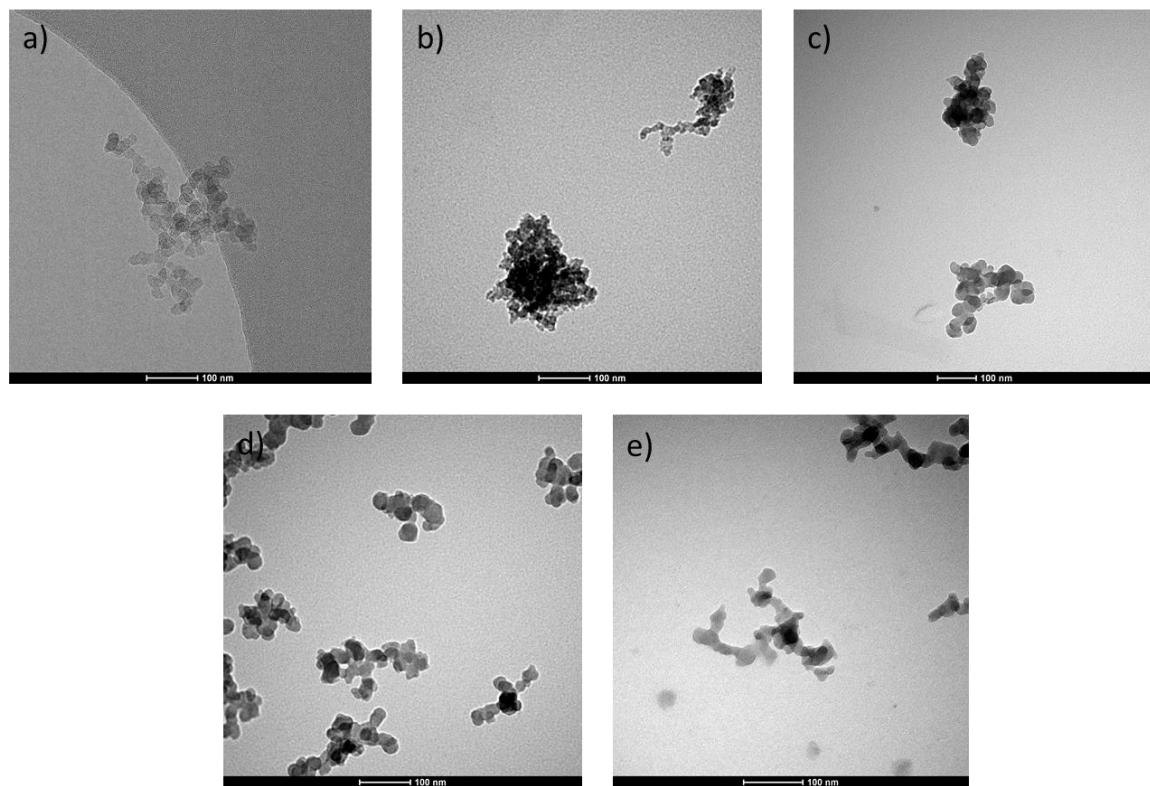

†† Expanded uncertainty ($k=2$, 95 % confidence interval) determined as the twofold standard deviation of at least 10 measurements.

The fractal dimension D_f of soot particles with a nominal GMD₅₀ of 100 nm was derived via image analysis of high-quality TEM images using the FracLac feature of ImageJ 1.53c (ImageJ, National Institutes of Health, USA). In a first step, the greyscale TEM images were converted into binary images utilizing the auto-convert function of FracLac. In a second step, the D_f values were determined via the so-called box counting, averaging 12 rotations of each image. The D_f values summarised in Table 1 represent the average values obtained from at least 10-20 particles for each type of soot. These values agree well with those reported in previous studies for bare (i.e. freshly emitted) soot particles (Pang et al., 2022; Wang et al., 2017).

The effective density was determined for the 100 nm setpoints using an Aerodynamic Aerosol Classifier (AAC, Cambustion, UK) and a DMA (TSI Inc., USA) as described in (Tavakoli and Olfert, 2014). The lowest effective

178 density ($0.35 \pm 0.02 \text{ g/cm}^3$) was found for particles generated by the miniCAST 6204 C. Considering that these
 179 particles contain a high amount of OC, this value might seem at first glance to be low, but can be explained by the
 180 highly fractal-like structure of soot (Fig. 2e). In comparison, the miniCAST 5201 BC produced particles with an
 181 effective density of $1.04 \pm 0.08 \text{ g/cm}^3$ when operated under fuel-rich conditions (i.e. high OC mass fraction), which
 182 is in line with the more compact structure as shown in (Ess et al., 2021b). Similarly, the MISG generated particles
 183 with an effective density of $0.91 \pm 0.02 \text{ g/cm}^3$. 100 nm particles generated by the bigCAST exhibited an
 184 intermediate effective density of $0.66 \pm 0.02 \text{ g/cm}^3$. [According to the summary work by Olfert and Rogak, the effective density of denuded soot from various sources \(gas turbines, compression ignition engines and laboratory-based burners\) lies typically in the range 0.4-0.8 g/cm³ at 100 nm mobility diameter \(Olfert and Rogak, 2019\).](#)
 185 [Compression-ignition engines tend to produce soot with higher effective densities, while gas-turbine soot tends to have lower effective densities \(Olfert and Rogak, 2019\).](#) ~~The results are in line with the~~ The calculated fractal
 186 dimension of soot particles [lied in the range 1.55 – 1.65 for all generators, in line with the fractal-like morphology](#)
 187 [observed in the TEM images and with previous studies on freshly emitted soot particles from different combustion](#)
 188 [sources \(Pang et al., 2023\), which increases from 1.54 for soot generated by the miniCAST 6204 C to 1.71 for](#)
 189 [soot generated by the MISG.](#)

193

194

195 **Figure 2: TEM images of polydisperse soot particles generated by a) the miniCAST 5201 BC (GMD_{mob} of ~100 nm, fuel-
 196 lean setpoint); b) the MISG (GMD_{mob} of ~100 nm); c) by the Euro 5b test vehicle (GMD_{mob} of ~55 nm); d) the prototype
 197 bigCAST (GMD_{mob} of ~100 nm); and e) by the miniCAST 6204 C (GMD_{mob} of ~100 nm). Further images are compiled
 198 in Figs. S2-S5 and in (Ess et al., 2021b).**

199 Soot particles generated by the bigCAST with a GMD_{mob} of ~ 100 nm consist of primary particles with a diameter
 200 $d_{pp} = 24.5 \text{ nm} \pm 1.8 \text{ nm}$, whereas those from miniCAST 5201 BC (fuel lean setpoint) have an average primary
 201 particle size of $12.3 \text{ nm} \pm 3.7 \text{ nm}$ at a similar GMD_{mob}. Soot generated by the MISG had a much smaller primary
 202 particle size (d_{pp} of $9.2 \text{ nm} \pm 3.8 \text{ nm}$). The TEM images in Figs. 2b and S3 revealed that some particles have a

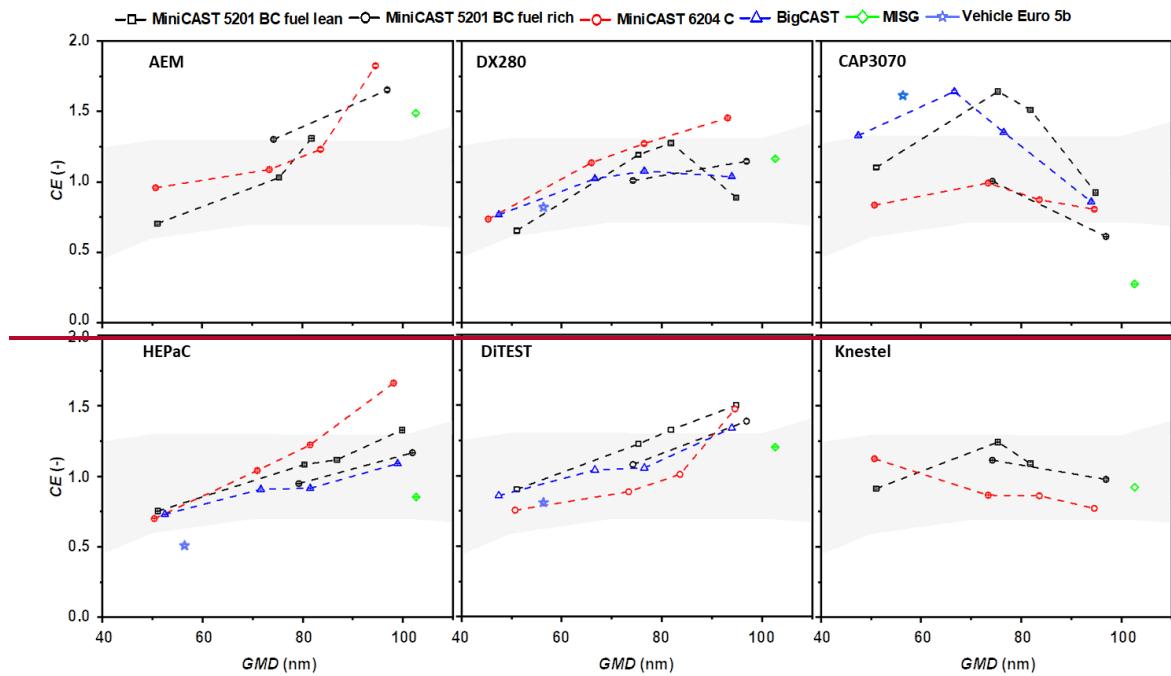

203 more compact soot structure than what reported by (Kazemimanesh et al., 2019) who used ethylene as fuel. This
204 observation is in line with the relatively high particle effective density (0.91 g/cm³) ~~and fractal dimension (1.71)~~
205 reported above.

206 **3.2 Counting efficiency (CE) profiles of PN-PTI counters**

207 The CE profiles of the PN-PTI instruments under test were determined by dividing the reported number
208 concentration by that measured with a reference condensation particle counter (NPET 3795, TSI Inc., USA). The
209 counting efficiency of the reference counter was taken into account during the data analysis.

210 Figure 3 summarises the results obtained with the various laboratory-based combustion generators and the Euro
211 5b diesel vehicle. In general, the CE of PN-PTI instruments increased with increasing GMD_{mob}, in line with
212 previous studies (Melas et al., 2023; Vasilatou et al., 2023). In the case of CAP3070, CE started to decrease at
213 GMD_{mob} ≥ 65 nm, most probably due to built-in correction factors. It cannot be ruled out that the measurement
214 principle of the instrument, based on the so-called escaping current principle, plays also a role (Lehtimäki, 1983).
215 In general, for each PN-PTI instrument, the differences in CE when challenged with different soot aerosols of
216 similar particle size were <0.25 at 50 nm and increased with size, but remained typically lower than 0.5. Higher
217 differences were observed for CAP3070 at around 100 nm, probably related to the internal correction factors. This
218 indicates that the exact morphology (e.g. primary particle size, effective density) of the test aerosol had an effect
219 on instrument performance as expected from previous studies (Dhaniyala et al., 2011). The response of each PN-
220 PTI model was, however, individual, making it difficult to draw any general trends. For instance, the CE of the
221 HEPAc was higher when measuring soot particles from the miniCAST 6204 C compared to soot of similar
222 GMD_{mob} from the bigCAST. CAP3070 showed the opposite behaviour. At a GMD_{mob} of ~100 nm, DX280
223 exhibited a higher CE with soot particles generated by the miniCAST 5201 BC under fuel-rich conditions (i.e.
224 lower EC/TC mass fraction) than at fuel-lean conditions (higher EC/TC mass fraction). CAP3070 showed again
225 the opposite behaviour. It is also worth mentioning that for the HEPAc and DX280 instruments the measured CE
226 values scattered more at particle sizes larger than 90 nm. This supports the choice of soot with 50-90 nm mobility
227 diameter for the PN-PTI instruments verification linearity tests. The counting efficiency of the different PN-PTI
228 counters as a function of time is shown in Figs. S6-S9 for a measurement duration of 2 min.

229

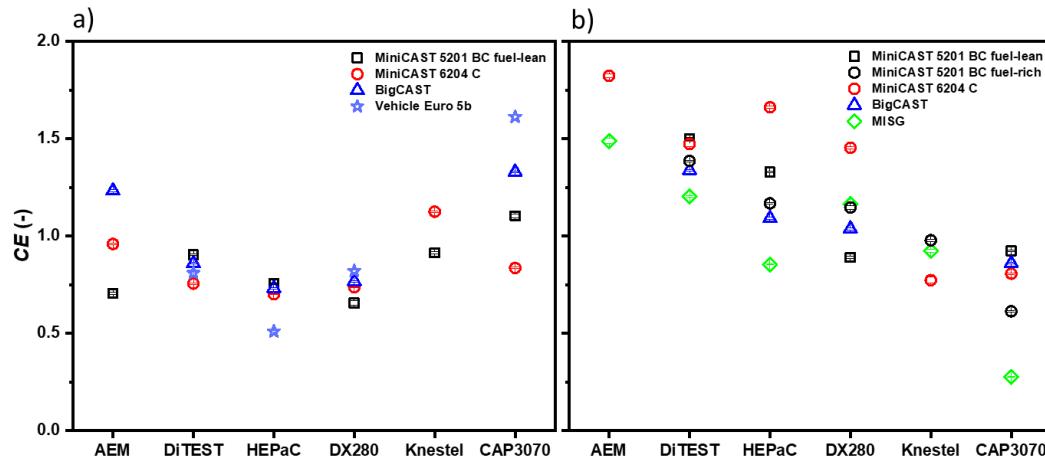

230

231 **Figure 3:** Influence of the type of soot generator/vehicle engine (bigCAST, miniCAST 5201 BC, miniCAST 6204 C, MISG and Euro 5b diesel engine) on the counting efficiency (CE) of six different PN-PTI counters: AEM, HEPaC, 232 DiTEST, CAP3070, DX280, and Knestel. The grey-shaded area designates the upper and lower limits in the counting 233 efficiency as defined in the document "Commission Recommendation on particle number measurement for the periodic 234 technical inspection of vehicles equipped with compression ignition engines" (EU, 2023). 235

236 In the case of the DX280 and DiTEST, the CEs reported for the laboratory-generated soot (GMD_{mob} of about 50- 237 55 nm) showed an excellent agreement with the CE measured for diesel soot from a Euro 5b vehicle as shown in 238 Fig. 4a. In all other cases, deviations were observed. These remained typically within 0.25 units in CE but in one 239 case (for CAP3070) reached a factor of 2. Note that for real vehicle exhaust the tolerance (maximum permissible 240 error MPE) according to German regulations is $\pm 50\%$ (PTB, 2021). In general, the data indicate that soot produced

241 by miniCAST and bigCAST generators simulate, in most cases, the properties of diesel soot by a Euro 5b vehicle
 242 satisfactorily.

243
 244 **Figure 4: Influence of the type of soot generator/engine (bigCAST, miniCAST 5201 BC, miniCAST 6204 C, MISG, Euro**
 245 **5b vehicle) on the counting efficiencies (CE) of six different PN-PTI counters: AEM, HEPaC, DiTEST, CAP3070,**
 246 **DX280, Knestel (the Knestel and AEM counters were not challenged with the Euro 5b vehicle since the Knestel counter**
 247 **was sent for service and the performance of the AEM counter deteriorated during the measurement campaign at JRC).**
 248 **The polydisperse test aerosols had a particle number concentration of ~100'000 cm⁻³ and a GMD_{mob} of a) 50-55 nm and**
 249 **b) ~ 100 nm.**

250 As shown in Fig 4b, soot generated by the MISG ($GMD_{mob} \sim 100$ nm) led to CEs close to 1 for the DX280,
 251 DiTEST, Knestel and HEPaC counters, and the CEs lied within the tolerance range defined in Germany and
 252 Switzerland (the Netherlands and Belgium only specify a tolerance range for mobility diameters up to 80 nm). The
 253 CE limit values were only exceeded in the case of the AEM and CAP3070 counters but this was most probably
 254 due to a deterioration of the performance of the AEM instrument or an underestimated internal correction and an
 255 overestimated internal correction factor in the case of CAP3070. Although the size of the soot generated by the
 256 MISG ($GMD_{mob} \geq 90$ nm) tends to be larger than real soot from diesel engines (Kazemimanesh et al., 2019;
 257 Moallemi et al., 2019; Senaratne et al., 2023), its ease of operation combined with the affordable price make it an
 258 attractive choice for PN-PTI verification in the laboratory.

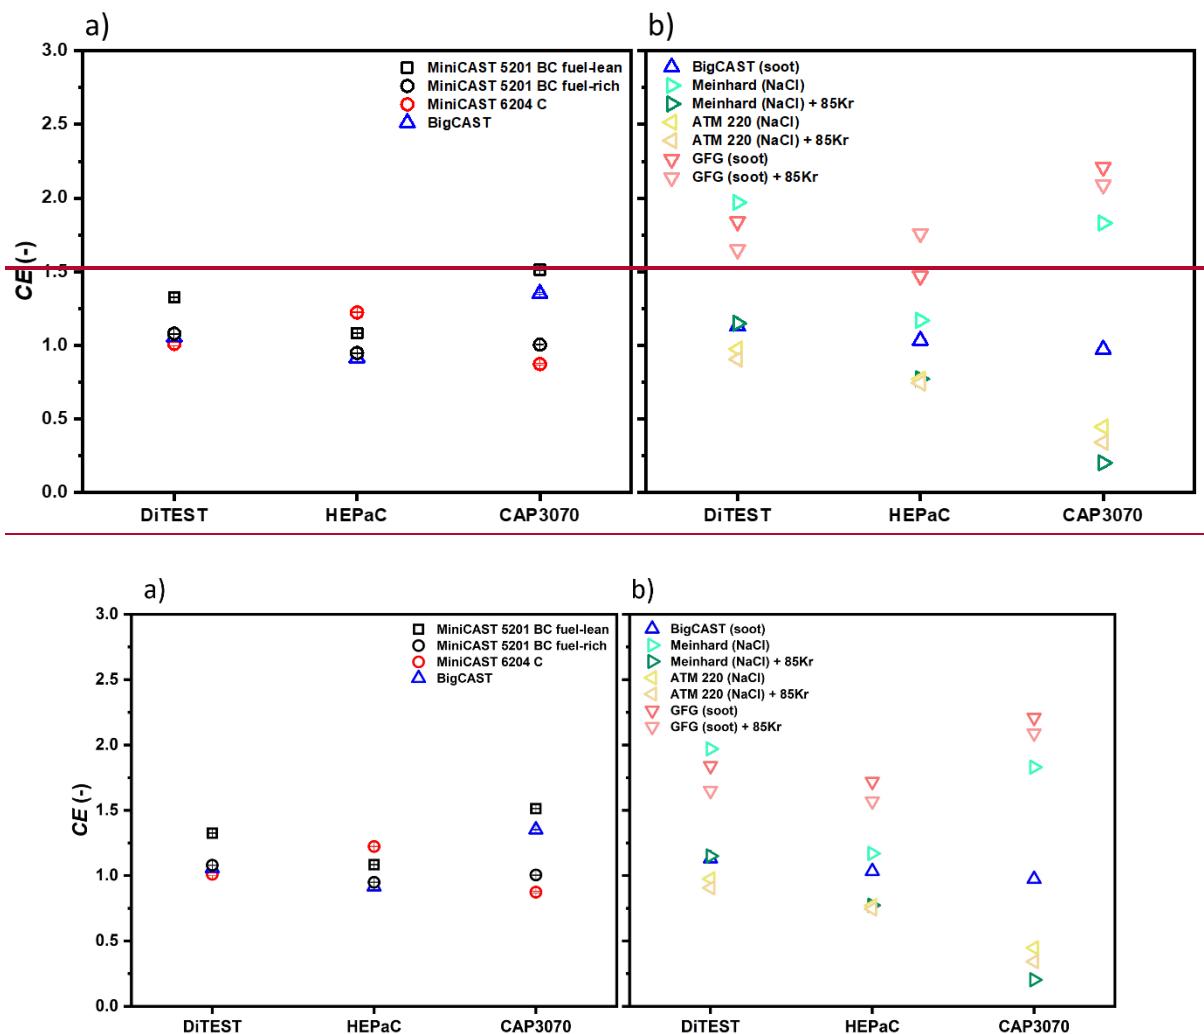

Figure 5: a) Influence of different soot aerosols with a GMD_{mob} of ~80 nm on the counting efficiencies (CE) of three different PN-PTI counters. b) Influence of different test aerosols (soot, NaCl and carbonaceous particles from a spark-discharge generator) on the counting efficiencies (CE) of the same PN-PTI counters. The test aerosols had a GMD_{mob} of ~80 nm. The data points are taken from (Vasilatou et al., 2023).

The variation in the counting efficiency of the PN-PTI instruments when tested with soot particles from different combustion generators (Fig. 5a) is much smaller than that observed with test aerosols such as NaCl or particles from a spark-discharge generator with a similar GMD_{mob} (Fig. 5b) (Vasilatou et al., 2023). For instance, carbonaceous particles from a GFG spark-discharge generator (Palas GmbH, Germany) led to a CE of ≥ 2 in the case of CAP3070 and 1.7-1.8 in the case of DiTEST. On the contrary, CE remained typically in the range 0.7-1.3 when soot was used as test aerosol, irrespective of the type of combustion generator (Fig. 5a). Further studies with more diesel test vehicles would be necessary to elucidate which type of laboratory-generated soot is the best proxy for diesel soot, keeping in mind that the properties of real diesel soot can also differ considerably, depending on the engine design, driving cycle and fuel properties (Hay et al., 2017; Wihsaari et al., 2020).

275 **4 Recommendations**

276 Based on the results of this [and previous studies](#) (Vasilatou et al., 2023), the following recommendations can be
277 made:

278 1) Initial and follow-up verification of DC-based PN-PTI counters should ideally be performed with soot as test
279 aerosol. If possible, the same type of combustion generator should be used for the determination of CE during
280 type-examination and verification.

281 2) Low-cost soot generators can be a stable source of combustion particles and can be employed for PN-PTI
282 verification using the appropriate setup correction factors. However, the GMD they produce should be in the
283 range 70 ± 20 nm in order to comply with the current linearity verification requirements in Europe.

284 3) Laboratory procedures for PN-PTI type-examination and verification should be further harmonised in Europe
285 to avoid inconsistencies in the enforcement of PTI legislation. International round robin tests should be
286 performed to examine whether a) the various PN-PTI instruments type-examined and verified in different
287 European countries according to national regulations exhibit a similar performance and b) whether PN-PTI
288 instruments verified in the same country but with different test aerosols identify defect DPFs in a consistent
289 manner.

290 As highlighted in our previous study (Vasilatou et al., 2023), “setup correction factors” should be determined
291 whenever verification is performed with particles other than soot to account for the effects of the test aerosol on
292 the instrument’s counting efficiency. These “setup correction factors” depend on both the aerosol physicochemical
293 properties and the instrument’s design, and need to be determined at the NMI level at regular intervals as drifts in
294 the performance of the aerosol generator may occur. If “setup correction factors” are not applied or are inaccurate,
295 the reliability of PTI will be compromised. The use of “setup correction factors” is more critical when nebulisers
296 or spark-discharge generators are used, but special care should also be given to different flame soot generators.
297 This calls for a closer collaboration between NMIs, state authorities, instrument manufacturers and verification
298 centres to ensure fair implementation of regulations in Europe. Further harmonisation of the different PN-PTI
299 type-examination procedures in Europe, e.g. in terms of the combustion generator, would be a valuable first step
300 in order to determine meaningful correction factors for other test aerosols.

301 **5 Conclusions**

302 The type of soot aerosol [generated by diffusion and premixed flame generators](#) affected the response of six
303 different DC-based PN-PTI counters tested in this study. Size and physicochemical properties of the test aerosol
304 had effects on the CE of all counters, [but the effect was different for each counter](#). In most cases, the different
305 laboratory-generated soot aerosols resulted in deviations of 0.25 units in the counting efficiency of individual
306 counters compared to Euro 5b diesel soot at similar mobility diameters ($\sim 50-60$ nm). It is not entirely clear which
307 type of laboratory-generated soot is the best proxy for real soot emitted by diesel vehicles as the response of the
308 PN-PTI instruments to the different test aerosols was not uniform. It must also be kept in mind that the properties
309 of diesel soot may vary depending on the engine specification and operation. Nevertheless, [the differences](#)
310 [observed with different soot generators were much lower compared to previous studies that used NaCl and particles](#)
311 [from spark discharge generators. This study confirms that soot aerosols, irrespective of the generator model, are](#)
312 [more suitable as test aerosols for the PN-PTI application, but special attention should be given to differences that](#)

313 arise from different generator models or set points and consequently for their correction via appropriately defined
314 factors~~than NaCl, oil or particles from spark discharge generators~~. In view of these results, recommendations were
315 made with regard to PN-PTI type-examination and verification.

316 **Author contribution**

317 All authors designed the experiments. TH, DR and AM carried out the measurement campaigns. TH analysed the
318 data with support from DR. KV prepared the manuscript with contributions from all co-authors.

319 **Competing interests**

320 The authors declare no competing interests.

321 **Acknowledgements**

322 TH, DR, and KV would like to thank Kevin Auderset and Christian Wälchli (both at METAS) for technical support
323 and useful discussions. AM and BG would like to thank Dominique Lesueur and Andrea Bonamin for technical
324 support.

325 **Funding**

326 No external funding was used for this study.
