Abstract. Ultrafine particles play a crucial role in the atmosphere, both as a source of larger particles and as a factor influencing human health. We analysed hourly particle number size distributions collected during 2015–2021 from an urban background station in the Rhine-Main area in Germany, with a focus on multiannual trends and potential particle sources. The site is influenced by diffuse regional sources such as motor traffic and domestic heating, as well as Frankfurt Airport, located at a distance of 6 km. The average total particle number concentration (TNC, size range 10–500 nm) was $9.4 \times 10^3 \text{ cm}^{-3}$. TNC maxima were observed in diurnal cycles at 07:00, 13:00, and 21:00. The midday peak was more distinct during the warm season and dominated by nucleation mode particles (NUC, 10–30 nm), suggesting photochemical particle formation as a source. When the wind was blowing from Frankfurt airport, a 2.5-fold concentration average in NUC was observed compared to other directions ($11.2 \times 10^3 \text{ cm}^{-3}$ and $4.3 \times 10^3 \text{ cm}^{-3}$, 2015–2021). In 2020, during traffic restrictions related to the COVID-19 lockdown, TNC downwind of the airport was 40–60% lower compared to the average of the four years before. Overall trend analysis for 2015–2021 yielded consistent downward trends for TNC (–2%/year), atmospheric particulate matter PM₁₀ mass (4%/year) and nitrogen dioxide NO₂ (–5%/year). While our observations of particle number size distributions show general similarities to other Central European observations, the effect of winds from Frankfurt Airport as a particle source is most prominently seen in the range 10–30 nm. The airport's role as a source of NUC and the rise in flights from 2015 to 2019 may be the cause of lower decline rates when compared to other locations.

25

1. Introduction

Despite significant advances in aerosol and air quality science during recent years, important questions remain. The challenges relate to the attribution of sources for certain components of particulate matter (PM) in the atmosphere, including ultrafine particles (UFP; particles with a size < 100 nm in diameter), the effects of PM and UFP on atmospheric processes and climate, and their impacts upon human health. In this manuscript, we always use PM as an abbreviation for PM mass concentration.

Although the adverse health effects of UFP in long-term studies have not been ascertained (Cassee et al., 2019; Ohlwein et al., 2019), partly due to a lack of sufficient studies, the WHO has recommended concrete UFP levels as a “good practice statement” in its latest report (WHO, 2021). The WHO defines UFP as a total particle number concentration (TNC) with a lower size limit of 10 nm or less and an open upper end. WHO considers 24-hour means of TNC $< 1,000 \text{ cm}^{-3}$ “low concentrations” and TNC $> 10,000 \text{ cm}^{-3}$ “high concentrations”.

The temporal variability of particle number size distributions (PNSD) and UFP concentrations is complex due to dynamic processes such as meteorology, emissions and atmospheric processes such as new particle formation (NPF) (nucleation), evaporation, condensation, coagulation and deposition (Bousiotis et al., 2021; Yao et al., 2018).

UFP may have a high spatial and temporal variability in urban areas, as shown by mobile and stationary measurements (Trechera et al., 2023; von Schneidemesser et al., 2019). The major factors influencing UFP concentrations include time of day, wind direction, season, wind speed, temperature and solar radiation (von Bismarck-Osten et al., 2013) and the mixing layer height (MLH) (Emeis et al., 2008). The diurnal trend of UFP from traffic was described to be higher on weekdays with maximum concentration of nucleation mode particles (NUC, 10–30 nm) with max. at 15 nm in the morning rush hour (Wehner et al., 2002). Diurnal variations of UFP in San Francisco (USA) showed a summer midday peak that is not observed in other pollutants, indicating NPF (Gani et al., 2021). As evidenced by the evaluation of concurrent background and roadside measurements in Germany, NPF can contribute up to 30% of the NUC relative to other sources, including residential heating and car traffic (Ma and Birmili, 2015). NPF was the most important source by applying k-means clustering analysis, on average, for 16% of the particle size distributions of all days, especially in Southern Europe (Brines et al., 2015). Particles originating from secondary NPF contain relevant amounts of sulphate, amines and various organic compounds (Kerminen et al., 2018). Airborne measurements suggest that plumes from industrial plants contribute to 10–40% of background UFP in Germany (Junkermann et al., 2016). Several studies discuss the source apportionment of UFP (Garcia-Marlès et al., 2024; Hopke et al., 2022; Trechera et al., 2023; Vörösmarty et al., 2024). A recent study identified ten different sources and factors in urban Europe for PNSD: Nucleation (traffic-nucleation and photo nucleation), domestic heating, urban and regional background, among others (Garcia-Marlès et al., 2024).

Aircraft emit a large fraction of the UFP in the size of NUC particles (Brock et al., 2000). These NUC were primarily caused by VOC emissions (Rivas et al., 2020). In the UFP mass fraction, jet engine lubricants were found (Ungeheuer et al., 2021). Ambient PM₁₀ at an airport was found to contain specifically Ba, Zn, Mo, Cu, and Sb, with overall concentrations similar to road traffic hotspots (Amato et al., 2010). Also, high amounts of NO₂ are present in aircraft emissions (Carslaw et al., 2006).

Airports have been identified as a source of elevated UFP, especially in the NUC range, both in measurements and models (Lorentz et al., 2019; Stacey, 2019). Atmospheric observations downwind from airports typically show elevated UFP, especially in the NUC at about 5–10 km, changing to slightly higher particle diameter in

Aitken mode particles (AIT, 30–100 nm) with tower measurements >20 km, probably due to particle growth over some hours (Harrison et al., 2019; Keuken et al., 2015). Numerous observations report an enhancement of UFP in downwind air: Los Angeles (USA), 4-fold at 10 km (Hudda et al., 2014); Amsterdam (Netherlands), 3-fold at 7 km (Keuken et al., 2015); Boston (USA), 1.6 to 3-fold at 5 km (Hudda et al., 2018); Zurich (Switzerland), using a dispersion model, 2 to 10-fold at 3 km (Zhang et al., 2020); London (UK), 10-fold at 1.2 km (Masiol et al., 2017). Other studies used positive matrix factorisation and cluster analysis to determine airport contributions to UFP (Hopke et al., 2022; Masiol et al., 2017).

Data on atmospheric UFP have been collected over long enough time periods to identify trends. Long-term observations in North America suggest an increase in UFP over time (Chen et al., 2022). In Germany and Europe, however, a decrease was found (Sun et al., 2020; Trechera et al., 2023). This decrease was associated with efforts on air quality control, and the studies did not investigate the influence of aircraft emissions.

In this study, we analyse hourly PNSD collected during 2015–2021 from an urban background station in the Rhine-Main area in Germany. To identify the effects of potential particle sources, we examine PNSD and particle number concentration trends as a function of time of day, season, and wind direction. The main measurement site is influenced by dispersed regional sources such as motor traffic and domestic heating, as well as Frankfurt Airport (FRA), located at a distance of 6 km. These auxiliary measurements are obtained from official measurement sites in the same area. This work presents new data from the period 2015–2021 and elaborates on former investigations of UFP in the vicinity of FRA (Gregor et al., 2015), including spatially resolved measurements as well as trend analyses (Sun et al., 2020). We want to examine the impact of air pollution from anthropogenic sources like Frankfurt Airport, as well as NPF, on the local air quality, especially UFP concentrations. We also want to assess the specific impact of the COVID-19 lockdown with its traffic reductions (Putaud et al., 2021). According to our searches, this is the first study to examine the impact of an airport on a measurement site downwind over a 6-year period.

2. Methods

2.1. Study area

This study is based on atmospheric measurements in the Rhine-Main metropolitan region (2.8 million inhabitants), including the city of Frankfurt (Main). An essential feature is Frankfurt Airport (FRA), which ranked 4th to 6th in Europe with regard to passenger volume during 2015-2021. Observations were made at one site for PNSD and three other sites for auxiliary observations, shown in Fig. 1. For the exact positions of the sites, see Tab. 1.

For this study, we used PNSD data from the years 2015-2021, excluding 2016 resulting in a 6-year trend analysis. We excluded 2016 due to its low data coverage (<55%). PM mass concentration measurements at LAN lasted from January 1, 2019 to December 31, 2021.

Table 1. List of air quality sites supplying datasets to this study, with location and type of environment. Coord., coordinates; Alt., altitude; UB, urban background; Met, meteorological parameters; TC, traffic count.

Acronym	City (station name)	Parameters	Station type	Station Code	Coord.; (Alt., m a.s.l.)

- LAN (Langen) is the main observation site for particle number size distributions (PNSD). The urban background site is on the roof of the laboratory building of the German Environment Agency or Umweltbundesamt (UBA), in Langen, a mixed business/residential neighbourhood 1.5 km northwest of the city centre (approximately 40,000 residents). It lies 15 km south of Frankfurt (Main) and 15 km north of Darmstadt. Site classification and details can be found in Birmili et al., 2016 and Sun et al., 2020 for further information. Significant roads are located 500 m to the south (B486 federal road, ca. 24,000 vehicles/day, 6% heavy-duty vehicles), 3 km to the east (A661 motorway, ca. 70,000 vehicles/day, 6% heavy-duty vehicles), and 4 km to the west (A5 motorway, ca. 130,000 vehicles/day, 11% heavy-duty vehicles). An overview of parameters is given in table 1 and additional information in table S1.

We also used data from 3 auxiliary observation sites:

- **DAR** (Darmstadt) is an urban background site to supply general air quality data in the city of Darmstadt (Rudolf-Mueller-Anlage), 15 km south of LAN and 18 km southeast of Frankfurt Airport. It is operated by the governmental authority Hessian Agency for Nature Conservation, Environment and Geology (HLNUG) (HLNUG, 2023a). Hourly concentrations are provided: NO, NO₂, CO, O₃, SO₂, and PM₁₀ mass.
- **FFM_AP** (Frankfurt Airport) provides data on meteorological parameters. It is situated on flat grassland at the edge of the airport field. It is operated by the German Weather Service (DWD). Because

buildings and building components to the northeast were shaded by winds, we preferred the weather parameters from FFM_AP over LAN. For completeness, wind roses for both LAN and FFM_AP for 2015–2021 are given in the supplement (see Fig. S1).

- 130 • **LAN_TC** (Langen Traffic Count) is an automatic counting station for vehicular traffic at the edge of the B486 federal road, 1 km south of LAN. It is operated by the German Federal Highway Research Institute (BAST, 2023).

It is expected that traffic emissions from major highways and local roads less than five kilometres away, whose traffic count is recorded at the nearby station LAN_TC, will affect LAN measurements. Urban emissions such as domestic heating and limited industrial sources can be found in the surroundings of LAN. Natural gas is primarily used for domestic and commercial heating, with residential wood combustion likely to have increased recently. Residential wood combustion has been identified as the most important source of VOCs during winter in a city (Languille et al., 2020). There is a gas-fired power plant (DFS Energy Centre) 500 m to the north with 120 MWh fuel consumption per year (DFS, 2022).

140 A 430 MW coal-fired power plant in Frankfurt (Main), 11 km north, may be the primary source of SO₂ emissions. In Hesse, industry accounts for over 70% of the total 2000 t/a SO₂ emissions, with aircraft burning kerosene up to 300 m above ground contributing less than 10% (HLNUG, 2023b). The transport of polluted air from Eastern Europe to Eastern Germany is a major source of PM₁₀ mass (50%) and SO₂ (van Pixteren et al., 2019).

2.2. Instrumentation

145 The following instrumentation was used for atmospheric measurements at the main observation site, LAN: Particle number size distributions (PNSD) were measured by a Scanning Mobility Particle Size Spectrometer (MPSS). We used a TSI MPSS (TSI Inc., USA, model 3936), modified by Leibniz Institute for Tropospheric Research (TROPOS), Leipzig. The original TSI instrument was augmented with additional hardware and software from TROPOS, and Nafion® dryers were installed in the system for aerosol and sheath air conditioning.

150 We used the negative high voltage of the differential mobility analyser (DMA). As a condensation particle counter (CPC), TSI model 3010 was used before Nov 2016, and TSI model 3772 (both with a Dp₅₀ = 10 nm) afterwards. An X-Ray neutraliser (TSI model 3087) was used for bipolar charging of ambient aerosols. Prior to size classification, the aerosol was dried below 50% relative humidity (RH), as opposed to the optimal 40% RH (CEN, 2020). In this instance, hygroscopic characteristics and other water uptake processes may have caused the particles to grow, resulting in larger particle sizes and, as previously noted, an even higher proportion of NUC.

155 Humidity was between 40 and 50 percent 8 percent of the time, particularly during the summer months. After multiple charge inversion, the MPSS provides PNSD across a particle size range of 10–500 nm. Regular quality control was performed in association with the World Calibration Centre for Aerosol Physics (WCCAP), Leipzig, Germany. A Catalytic Stripper (Catalytic Instruments, CVF500) operating at 400°C was used since mid-2016 to

160 remove gas-phase hydrocarbons (1-butanol) from the exhaust of the CPCs.

To provide standardised sampling conditions, a PM₁ mass inlet (Digitel AG and sampling line PSE1, Riemer) was used at a total flow of 33 L min⁻¹, heated to 25°C. The temperature in the measurement container ranged between 20°C and 25°C, as controlled by a combination of air conditioning and heating. Although direct solar radiation heated the sampling line to 31°C during the summer, the aerosol was cooled to the temperature of the measurement container air as it passed through the sampling line and Nafion® dryers. As a result, the PNSD's temperature range of 5°C was ignored throughout the year. For more information, see Tab. S1. We are aware

165

that inlet heating is no longer recommended since 2020 and that the PM₁ mass inlet should be PM_{2.5} or PM₁₀ (CEN, 2020).

The meteorological parameters (FFM_{AP}) and the concentrations of PM mass and gaseous pollutants (DAR) were recorded at the corresponding nearby stations using instruments that comply with European legislation standards. All data obtained were averaged to hourly values.

2.3. Data treatment

The non-parametric Mann-Kendall test (Kendall, 1975; Mann, 1945) was used to determine an increasing or decreasing trend over time. In the presence of a statistically significant trend, the amount was quantified by the Theil-Sen slope. This is the median of all possible slopes between the data pairs (Sen, 1968; Theil, 1992). To accomplish this, monthly data series spanning more than 6 years were aggregated with a 30% threshold and de-seasonalized using the seasonal decomposition of time series by loess (Cleveland et al., 1990). It should be noted that a 6-year time series for identifying trends is quite short. Data preparation and statistical analysis were carried out with R (v3.6.1, (R Core Team, 2019)) and the Openair package (v2.18-2, 2024-03-11) (Carslaw and Ropkins, 2012). To better compare the contributions to exposure to an air pollutant between the modes, we have divided the 10° cut wind sectors into 20° or 30° sectors: northeast (NE) 40-60°; northwest (NW) 290-310°; southwest (SW) 190-220°. The TNC in this study has three particle modes: nucleation (NUC: 10-30 nm), Aitken (AIT: 30-100 nm), and accumulation (ACC: 100-500 nm). The specific size range for NUC often depends on the instrumentation used for measurement, the specific scientific question being addressed, and the environment being studied (e.g., urban, remote, marine). It is currently defined as 3-25 nm (Wehner et al., 2005) but with higher lower and upper limit for modelling aerosols 10-40 nm (Lupascu et al., 2015). Since the equipment we used only captures the larger portion we used 10 nm as the lower limit (Trechera et al., 2023) and extended the upper limit slightly to 30 nm. We are aware that the proportion of larger particles in the 500–800 nm range is not measured in accordance with CEN guidelines (2020).

3. Results and Discussion

3.1. Particle number size distributions and number concentrations

Table 2 presents the multiannual statistics of TNC-derived PNSD (10-500 nm). The corresponding data for the year 2021 is given in Table S3. The median TNC was $8.2 \times 10^3 \text{ cm}^{-3}$ ($7.9 \times 10^3 \text{ cm}^{-3}$ in 2021). The NUC range had the highest fraction of TNC (median $3.7 \times 10^3 \text{ cm}^{-3}$, 44% 2015-2021; $3.9 \times 10^3 \text{ cm}^{-3}$, 49% in 2021). These values are within the typical range of other urban background stations in Germany and Europe (Sun et al., 2020; Trechera et al., 2023). The highest 1% of hourly TNC ranged from 31 to $290 \times 10^3 \text{ cm}^{-3}$ for the entire period and from 27 to $54 \times 10^3 \text{ cm}^{-3}$ in 2021.

Table 2. Hourly Concentrations at Langen (LAN) 2015-2021 (2016 excluded) for nucleation, Aitken and accumulation mode particles (NUC, N10-30; AIT, N30-100, and ACC, N100-500) and total number concentration (TNC, N10-500). Data coverage in % per annum (p.a.)

PNC in 1/cm ³	Min .	1perc	Median	Mean	SD	99perc	Max	coverage (%)
TNC	572	1 806	8 286	9 352	6 082	30 930	289 689	71
NUC	79	572	3 699	4 996	5 082	24 349	271 376	71
AIT	112	441	2 772	3 191	2 009	9 738	17 915	71
ACC	22	130	1 009	1 165	792	3 615	21 547	71
N ₃₀₋₅₀₀	141	610	3 886	4 356	2 553	12 109	30 397	71

3.2. Temporal trend of TNC

Figure 2 shows the multiannual trend for TNC on the basis of seasonal averages, the seasons being defined as a 3-month period, i.e., winter corresponds to the months of December, January and February. The moving average of the trend shows a decrease for the 95th percentile and a drop of 25% in spring 2020.

Figure 2. Trend of seasonal means of TNC from 2015 to 2021 at LAN.

Figure 3a-c Theil-Sen trend (deseasoned) for monthly means from 2015 to 2021 for **all wind directions** for (a) LAN: TNC, DAR: (b) PM10, and (c) NO2.

Figure 4a-c. Theil-Sen trend (deseasoned) for monthly means, 2015-2021, from wind from airport: WR 270°-340°, for (a) LAN: TNC, DAR: (b) PM10 and (c) NO2.

Figure 5a-c. Theil-Sen trend (deseasoned) for monthly means, 2015-2021, from wind not from airport: WR 350°-360° + 0°-260°, for (a) LAN: TNC, DAR: (b) PM10 and (c) NO2.

For better representation, Fig. 3 shows trend lines according to Theil-Sen (s. 2.3) from 2015 to 2021 on the basis of monthly means of daily mean values (cf. Tab. S6). The trend for TNC (Fig. 3a) yielded a highly significant

($P < 0.001$) decrease of -2.3% per annum (p.a.). Even for the shorter period of 2015–2019 when excluding year
 220 2020 as a special year of pandemic-caused reductions, the trend was still -1.9 % p. a. but less significant ($P < 0.05$)
 (cf. Tab. S6). Trend analyses for an earlier period (2009–2018) at German Ultrafine Aerosol Network (GUAN)
 stations in Germany showed a stronger decrease between -2.6% to -6.3% p.a. for TNC (20–800 nm) (Sun et al.,
 2020). The airport as an additional source of NUC could be the reason for the lower decline rates compared to
 the other locations. When only wind from the airport is considered, the trend is higher (-3.7% per year, 2015 to
 225 2021, s. Fig. 4a). Here the pandemic year 2020 shows a dip before increasing again in 2021. This could be due
 to reduced emissions from the airport. The decrease in wind from the other directions was lower at -1.8% p.a.
 (Fig. 5a) and showed no visible impact in 2020.

Other components also showed a highly significant ($P < 0.001$) decrease, with even higher rates: PM₁₀ -4.3% p.a.
 (Fig. 3b) and NO₂ -4.9% p.a. (Fig. 3c). In contrast, some components showed a significant ($P < 0.01$) increase:
 230 CO 3.5% p.a., ozone 1.5% p.a. (cf. Tab. S4).

When considering Tab. S4 the decrease for the different particle size ranges was the highest for NUC -2.9% p.a.
 at $P < 0.001$ (2015–2021). The decrease was lower for AIT -2.0% p.a. (2015–2021). ACC showed no significant
 trend or even showed an increase of 3.3% p.a. 2015–2019. Overall, the decrease in TNC seems to be associated
 primarily with a decrease in the subfraction NUC. This decrease is in line with decreasing trends in other
 235 combustion-related compounds of mainly anthropogenic origin, such as NO₂, PM₁₀ and cf. Tab. S4 NO and SO₂.
 In contrast, CO, another combustion-related pollutant, increased as well as ozone.

The drop of 25% in 95th percentile in spring 2020 (Fig. 2) corresponded to the COVID-19-lockdown-related
 decrease in landings and take-offs (LTO) by 70% (Schultheiß-Münch et al., 2022) (s. 3.6) and car traffic on
 motorways by 16% (BAST, 2023) in 2020 compared to 2019 for car traffic (at LAN_TC) and 2015–2019 for
 240 airports. Several studies have examined the environmental impacts of traffic restrictions during the COVID-19
 lockdown. In Spain, COVID-19 lockdown restrictions reduced traffic intensity by up to 80%, resulting in lower
 levels of combustion-related pollutants NO₂, CO, and SO₂ (Putaud et al., 2021; Querol et al., 2021).

Figure S2 shows annual box plots for TNC to complete the picture. The yearly medians confirm the general
 downward trend.

245 3.3. Influence of sources and meteorological parameters

In this section, we analyse the variations of PNSD and its subfractions as a function of different meteorological
 variables. For the analysis of the temporal variation of the auxiliary compounds, we focus on the available data
 from 2019 to 2021.

250 3.3.1. Influence of wind direction on particle number concentrations

Figure 6 shows the average particle number concentration of all the years included in this analysis for each
 subfraction of the PNSD as a function of wind direction (aggregated to 10° steps) and wind speed (as distance
 from the centre). From this figure we can see high concentrations coming from the direction of the airport (NW
 indicated with a white arrow) with a maximum of $16 \times 10^3 \text{ cm}^{-3}$ for NUC. However, from this figure alone, it
 255 is unclear which factors influence the other size fractions AIT (Fig. 6b) and ACC (Fig. 6c) showing a maximum
 which could originate from various directions. Therefore, we analyse further by splitting the polar plot into the
 different years as shown in Fig. 7.

260 **Figure 6. Polarplot for particles in cm^{-3} , average of hours of the years 2015–2021 (2016 excluded), in LAN. (a) NUC, (b) AIT and (c) ACC. Grey spots represent cases less than 2 hours. The arrow indicates the wind from the airport.**

In 2020 (Fig. 6a), the lowest maximum value of NUC was observed with $7 \times 10^3 \text{ cm}^{-3}$ from the NW, which was reduced to 50% compared to the average of all previous years and which also had the lowest air traffic according to the Frankfurt Airport Air Traffic Statistics 2023 (Schultheiß-Münch et al., 2024) (s. 3.2). The maximum increased again in 2021. The highest 10° concentration was measured in 2018 from the NW at 9 m/s with $20 \times 10^3 \text{ cm}^{-3}$. In 2021, NW showed lower concentrations of $12 \times 10^3 \text{ cm}^{-3}$ than in the years before 2020, with $12 - 20 \times 10^3 \text{ cm}^{-3}$. We conclude that the airport 6 kilometres away has a strong influence on NUC concentrations.

270 AIT concentrations were highest in three directions: NW, NE, and S, reaching up to $4.5 \times 10^3 \text{ cm}^{-3}$ at wind speeds of less than 3 m/s. The lowest concentration was observed from the SW with a 10 times lower concentration of $0.5 \times 10^3 \text{ cm}^{-3}$. Figure 7b depicts the development of the average individual years. The highest concentration was recorded in 2017 from all directions at $< 1 \text{ m/s}$, while the lowest concentration was in 2020 with SW winds at 15 m/s.

275 The highest concentration ACC of $1.6 \times 10^3 \text{ cm}^{-3}$ was measured from all directions at $< 2 \text{ m/s}$. The second-highest concentration was $1.2 \times 10^3 \text{ cm}^{-3}$ and came from the E at 7 m/s. Figure 7c depicts the development of the average individual years. The maximum was found in 2018 from E at 5 m/s with $1.8 \times 10^3 \text{ cm}^{-3}$. The minimum in 2019 and 2020 from SW was $< 0.1 \times 10^3 \text{ cm}^{-3}$.

The 2019–2021 PM concentration polar diagrams in LAN and DAR showed a pattern that was similar to ACC (Fig. S3a, b). The highest concentration was found in the NE quadrant, especially in 2019 and 2021, with wind speeds of 10 m/s from NNE.

Figure S4 depicts the average NO_2 concentrations in the DAR over different years. Concentrations are highest from the northwest at 10 m/s and lowest from the southwest at wind speeds ranging from 0.5 to 5 m/s throughout the years. The NO_2 pattern appears to be partly influenced by the FRA airport, located 18 km away, and local sources. But the highest concentration from NW was not found in 2019 like with NUC, possibly due to the changing ratio between NO_2 and NUC from 2015 to 2019.

Figure 7: Polarplot for particles in cm⁻³, average of hours separated from 2015 to 2021 (excluding 2016), in LAN. (a) NUC, (b) AIT and (c) ACC. Grey spots represent cases less than 2 hours.

In contrast to NUC, wherein the highest concentration is in the direction of the airport, like in other studies before (Keuken et al., 2015), AIT and ACC showed a different pattern that is not directed towards the airport. These bigger particles could be influenced less by air traffic and more by other sources, such as tailpipe emissions, abrasion and resuspension or long-range transport (Okuljar et al., 2021). We speculate that AIT has sources in the traffic sector, in line with the arguments of Trechera et al., 2023. We interpret the pattern of ACC to the movement of large-scale meteorological air masses across Central Europe, as described in (Engler et al., 2007). In line with ACC, high PM₁₀ concentrations from NE with higher wind speed point to long-range transport effects (van Pixteren et al., 2019).

3.3.2. Seasonal variability

The annual variation for the entire period of TNC showed a maximum in summer, with the highest concentrations in July and August, and about 20% higher concentrations during May-September compared to the rest of the year. (See Fig. S5, where shaded areas represent 75% and 95% confidence intervals). TNC followed the same pattern as particles < 100 nm, as both NUC and AIT reached their maximums in summer (Jul-Aug). In contrast, ACC did not show pronounced maxima. For a comparison with airport traffic, cf. chapter 3.6.

We found a seasonal variability for PM₁, PM_{2.5} and PM₁₀, with a winter-to-summer ratio of 2-3 for PM_{2.5} in LAN (Fig. S6). The PM₁₀ concentration in DAR is lower in November and December than in LAN.

The secondary parameter ozone showed its maximum in summer; others such as NO₂, NO and CO showed their maxima in winter (Fig. S7).

For UFP at LAN and gaseous compounds at DAR, we discovered that TNC, NUC, AIT, and ozone have an annual cycle, with the highest concentrations in the summer. In contrast, PM, particularly PM_{2.5}, NO₂, NO, and CO, reached their peak in the winter. Possibly due to higher heating emissions and lower MLH in the winter.

3.3.3. Diurnal variation

In this section we analyse diurnal variation of particle number concentrations which are influenced by meteorology (temperature, humidity, wind speed), anthropogenic activities, and biological processes.

315 In LAN, the overall diurnal variation (Fig. 6a) of TNC showed two intermediate maxima concentrations (08, 21:00). First between 7 and 9:00 and a very small midday peak at 13:00 (Fig. S5) and the highest peak was seen at 21:00 in the evening. For NUC, a similar shape was observed, but with a more distinct small midday peak at 13:00 and a slightly earlier evening peak at 20:00. Hourly variations of NUC increased with ozone and global radiation (GLO) between 7:00 and 11:00 (see Fig. 8b), particularly in the summer, but less in the spring and autumn. The midday TNC peak was more pronounced in the summer and less so in the spring and autumn, but it was absent in the winter.

Diurnal variations of AIT and ACC showed the highest concentration between 20:00 and 2:00, especially during Friday and Saturday nights (Fig. S5). ACC showed a second maximum between 7:00 and 9:00, during the week, but not on weekends.

325 In LAN 2019–21, we found diurnal variability for PM₁, PM_{2.5}, and PM₁₀, with PM₁ having a (Fig. S6) minimum between 15 and 18:00. In contrast, PM₁₀ in DAR showed a profile with a maximum concentration during rush hour at 8:00 and a minimum concentration in the morning hours of 3–4:00. On average, the diurnal variability during 2015–2021 was similar to LAN in 2019–2021.

330 Ozone showed a midday peak at 15:00 (Fig. S7) and a minimum at 7:00. In contrast, NO, NO₂, and CO showed two peaks at 08–10:00 and 20–22:00 (see Fig. S7 and S8). SO₂ showed the highest concentration between 09:00 and 13:00.

Figure 8. The diurnal variation of hourly means, 2019–2021, NUC, TNC, GLO and O₃ in LAN (a); and for the 4 seasons separately (b). Shaded areas represent 75% and 95% confidence intervals.

335 The TNC concentration showed three peak concentrations. The first is between 7 and 9:00 a.m. during traffic rush hours, which could be due to aircraft activity, as observed in many previous studies (Sun et al., 2019; Trechera et al., 2023) and traffic influence, with the highest peak between 6 and 10:00 a.m. (Wehner et al., 2002). In LAN (see Fig. S5), we also see a small late morning-midday TNC peak. The TNC midday peak was lower than the concentrations during the traffic rush hour peak, but higher for NUC. The highest concentrations were found during night hours 21:00–0:00, probably due to night inversion.

The high midday TNC peak is attributed to regional or urban photo-nucleation and fumigation from higher atmospheric layers (rich in nucleation mode UFP and ozone) as the MLH grows due to convective dynamics, aviation, and/or power plants. In these measured cases, TNC peaks in the summer. This was observed with a

higher midday peak in summer, compared to none in winter (see Fig. 8), which was attributed to photo-nucleation.

ACC showed a peak during morning rush hours on weekdays, indicating that car traffic was the source of this peak. Similarly, also NO, NO₂ showed higher peaks during rush hours on weekdays than on working weekdays (Fig. S5, S7).

CO showed a pattern for the evening/night peak independently of the weekday day indicating non-traffic sources, but the morning peak was reduced on Saturdays and even vanished on Sundays (Fig. S8).

3.3.4. Weekday variations

On Sundays, NUC (-20%) and TNC (-15%) were reduced compared to working weekdays (Fig. S5). Hourly variations during the week show that the maximum of the afternoon peak varies in relation to the morning peak from weekday to weekend. Diurnal variations of AIT showed the highest concentrations between 20 - 2:00 on Friday and Saturday nights. AIT was highest on Saturdays (Fig. S5). On the weekends, ACC was only slightly higher. We found a day of the week variability for PM₁₀ in LAN and DAR (Fig. S6). Highest concentration on Wednesdays/Thursdays and lowest on Sundays, with a difference of 3 $\mu\text{g}\times\text{m}^{-3}$. PM₁₀ concentrations were similar on Saturdays and Mondays.

NO and NO₂ were highest during the week, with a minimum on Sunday (-25% NO₂). Ozone showed the inverse behaviour, with a maximum on Sunday and lowest during the working days. CO was slightly lower, and SO₂ showed a clearer minimum on Sundays.

We found on Sundays reduced concentrations of NUC, TNC and NO₂ (and less CO). Also, from 2015 to 2021, on average, 54% less traffic was counted at LAN_TC on Sundays than on Tuesdays through Thursdays (BAST, 2023). Therefore, we assume that the number of 10 – 30 nm particles was partly raised by car traffic during working weekdays, besides other causes like NPF. The afternoon NUC peak shifted from weekday to weekend. This might reveal that NUC and TNC were influenced by traffic. It is possible that the NUC-NPF peak in the afternoon is supplemented by the traffic-NUC peak, which decreases after traffic rush hours and is also reduced on Sundays.

Higher concentrations of AIT and, to a lesser extent, ACC, particularly at night before and after Saturday, may indicate the influence of increased barbecue and residential wood heating activity over the weekend in the nearby residential area, resulting in higher emissions of these larger particle modes. It is known that the combustion of solid fuels produces distributions with a modal diameter of approximately 100 nm (Hopke et al., 2022), which falls within both AIT and ACC. Wood burning activities are also associated with higher benzene concentrations at 18:00 elsewhere (Hellén et al., 2008).

3.4. Correlation of particle modes with auxiliary pollutants and meteorological parameters 2021

Due to the start of availability for PM in LAN from 2019 on, and because the COVID-19 lockdown caused a reduction in traffic in 2020, we focus on the year 2021 to compare different measured parameters with each other. The average concentration of four size modes and PM fractions, meteorological parameters and auxiliary pollutants can be found in the Table S3 with a coverage rate between 92 and 100%.

The mean concentrations in DAR in 2021 were PM₁₀ 13 $\mu\text{g}\times\text{m}^{-3}$; NO 4 $\mu\text{g}\times\text{m}^{-3}$; NO₂ 17 $\mu\text{g}\times\text{m}^{-3}$; CO 0.2 $\text{mg}\times\text{m}^{-3}$; SO₂ 0.8 $\mu\text{g}\times\text{m}^{-3}$; Ozone 42 $\mu\text{g}\times\text{m}^{-3}$. In LAN: PM₁₀ 14 $\mu\text{g}\times\text{m}^{-3}$, PM_{2.5} 10 $\mu\text{g}\times\text{m}^{-3}$ and PM₁ 9 $\mu\text{g}\times\text{m}^{-3}$, TNC $8.3\times10^3\text{ cm}^{-3}$, NUC $4.9\times10^3\text{ cm}^{-3}$, AIT $2.9\times10^3\text{ cm}^{-3}$, ACC $1.0\times10^3\text{ cm}^{-3}$.

The matrix in Fig. S9 shows the correlations between different particle fractions and auxiliary parameters in 2021. The particle number of TNC showed a significantly high to moderate correlation with NUC and AIT ($R = 0.90$ and $R = 0.64$) respectively, but a low correlation with ACC ($R = 0.26$). The LAN PM_{10} correlated highly and significantly with LAN PM_1 and LAN $PM_{2.5}$ ($R = 0.73, 0.88$) but showed a low negative correlation with NUC ($R = -0.08$).

NO_2 in DAR correlated moderately with $PM_{2.5}$ but not significantly ($R = 0.44$) and not with NUC ($R = 0.09$). NO_2 correlated highest with CO as another traffic-related pollutant ($R = 0.73$). SO_2 only correlated very low with NO_2 and PM fractions ($R = 0.18$ and $R = 0.15-0.17$). Ozone correlated moderately with temperature and global radiation ($R = 0.52, 0.45$), but not with any of the particle fractions. Concerning the meteorological parameters, a low positive correlation is obtained for both TNC and NUC (N10-30) with temperature ($R = 0.22$ to 0.23) and a very low negative correlation with RH ($R = -0.06$ to -0.09). Negative correlations were also observed for wind speed with all size modes, moderate for AIT and ACC ($R = -0.51$) and low for NUC ($R = -0.11$). Using a multiple linear regression approach, temperature and wind speed were two of the six most influential parameters for the spatio-temporal variance of UFP (von Bismarck-Osten et al., 2013).

3.5. Comparison with the WHO classification

According to the WHO definition of UFP, TNC has a lower limit of ≤ 10 nm and no restriction on the upper limit (WHO, 2021). The WHO classifies high concentrations as days $> 10,000 \text{ cm}^{-3}$ or hours $> 20,000 \text{ cm}^{-3}$. We discovered high concentrations in LAN on 23-59% of days and 2-6% of hours per year (see Tab. S 5). The WHO limit for high UFP in 24 hours per year was exceeded on 30% of all days. During the lockdown, there were fewer exceedances (23% per day and 2% of hours) than in previous years (37-59% of days and 5-6%). Considering the WHO classification for low concentrations per day ($< 1,000 \text{ cm}^{-3}$), no day of the entire measurement campaign was in this category.

These findings are limited to this specific location and time period of campaign. In the future, these results should be compared with data from other stations to further discuss their representativeness for similar station types and other local specific sources.

3.6. Temporal variability of emissions from the airport

To estimate the temporal variability of emissions from air traffic at Frankfurt Airport, we show the variability of flight activity measured in terms of passengers carried (PAX) and aircraft movements such as landings and take-offs (LTO).

Between 2015 and 2019, PAX at FRA averaged 65 million per year and increased by 2% per year (Schultheiß-Münch et al., 2022). PAX fell to 29% in 2020 and 38% in 2021, compared to previous years' averages. The LTO (490,000 on average) declined to 44% / 55% in 2020 / 2021. In 2023, the PAX and LTO were 90% of those in 2015-2019 (Schultheiß-Münch et al., 2024). The 95th percentile of the TNC fell by 25% in spring 2020 compared to the previous year (see Fig. 2) before rising again. In Fig. 3a, the monthly mean values from the airport's wind sector also show a constant average of $17 \times 10^3 \text{ cm}^{-3}$ in 2015-19, falling to $12 \times 10^3 \text{ cm}^{-3}$ in 2020 and then rising again slightly to $14 \times 10^3 \text{ cm}^{-3}$. This could also indicate that lower air traffic results in a lower maximum TNC.

The seasonal behaviour in 2023 is expected to be similar to the years preceding 2020. LTO has a seasonal maximum plateau from June to October and a minimum in February, with approximately 70% of the maximum

(Schultheiß-Münch et al., 2024). TNC follows a similar pattern to LTO, with a maximum in the summer, highest in July and August, and approximately 20% higher concentrations from May to September compared to the remainder of the year. As a result, this time pattern could also indicate TNC caused by aircraft movements other than the new NPF in the summer (s. 3.3.2).

The LTO's 24-hour fluctuation from 2015 to 2021 is characterised by a ban on night flights between 23 and 5:00 since 2011, with some exceptions, such as approximately 3% of the maximum daytime hours in 2019 (Gemeinnützige Umwelthaus GmbH, 2025). In 2019, the LTO is 0% between 0 and 5:00, and 30% from 5:00 to 7:00. Highest between 7 and 22:00 with 80 to 100%: The three maxima are 7-13:00, 16:00, and 20:00, with the lowest at 18-19:00 at 80%. As described in 3.3.3, NUC had a similar shape with three maxima (08, 13, 21:00), but with a clearer small midday peak at 13:00 than TNC did. The TNC midday peak was most noticeable in the summer and completely absent in the winter. Because the LTO diurnal cycle is consistent throughout the year, this midday peak appears to be unaffected by air traffic, or at least less so than the NPF.

Previous short-term studies of UFP near FRA, including spatially resolved measurements (Gregor et al., 2015), demonstrated that FRA is a source of UFP, particularly for small diameters in the NUC range. Atmospheric observations downwind of airports generally show increased UFP, especially in the NUC range (Harrison et al., 2019; Hudda et al., 2014; Keuken et al., 2015). Elsewhere, it is discussed that regional or urban photochemical NPF is not exclusively the cause of the high nucleation mode. An influence of airports is also described (Rivas et al., 2020)

3.7. Experimental Challenges

The experimental challenges we had to face were:

- In the LAN data set 2015-2019, high particle number concentrations were detected in the finest size fractions (Trechera et al., 2023). A measurement in the 10 nm range places high demands on instrumental detection, as the CPC used has a low detection efficiency in that range. Therefore, instrument-to-instrument variability has been observed to be higher below 20 nm than above this size (Wiedensohler et al., 2012). However, this higher variability has considerable effects, especially on the number concentrations in NUC.
- This study is based on a particle number size distribution (PNSD) dataset from 2015-2021, as well as auxiliary pollutants collected from a federal state authority's air quality monitoring network. It is also worth noting that all datasets had more than 55% data coverage during the study period; one year was excluded due to low data coverage. This shortfall could be attributed to the complexities of UFP-PNSD measurements, as well as the need for close supervision and frequent instrumentation maintenance.
- We recommend that future studies meet the UFP measurement requirements of ACTRIS and CEN (CEN, 2023, 2020), as well as Wiedensohler et al., 2018, 2012. Therefore, in future we will use an adapted MPSS of TROPOS for PNSD from 10 to 800 nm, including improved sampling according to CEN. Then, we will dry the sampled aerosol below 40% RH and use a PM_{2.5} inlet as is recommended in the Service Tool 1 prepared within the "Research Infrastructures Services Reinforcing Air Quality Monitoring Capacities in European Urban & Industrial AreaS" EU-project (RI-URBANS, 2024).
- The longer distance, particularly between the two stations LAN and DAR, made it difficult to adequately compare the gaseous pollutants to UFP.

4. Conclusions

- The effect of airport emissions upon the particle number concentration and 3 size classes starting from 10 nm was assessed at a site 6 km downwind from a major European airport (FRA) serving the Metropolitan region Rhine-Main (Frankfurt (Main)).
- 465 • Wind-influenced concentration analysis indicates that FRA is a strong potential source for nucleation and partly also for Aitken mode particles in an urban background station downwind from the airport. The average NUC concentrations were 2.5 times higher with wind from the airport than with other wind directions. We therefore draw the conclusion that aircraft emissions from a major airport within a 6-kilometer radius seem to have an impact on NUC.
- 470 • We discuss the value of long-term observations in understanding trends and investigating the effects of global events like pandemics on air pollution. In the COVID-19-lockdown-influenced year 2020, with the lowest flight traffic, the maximum TNC from airport direction was reduced to 25% of the previous year's average, the lowest maximum in 6 years.
- The WHO limit for high UFP in 24 hours ($> 10,000 \text{ cm}^{-3}$) per year was exceeded on 30% of all days.
