## S1. Small particle generation system

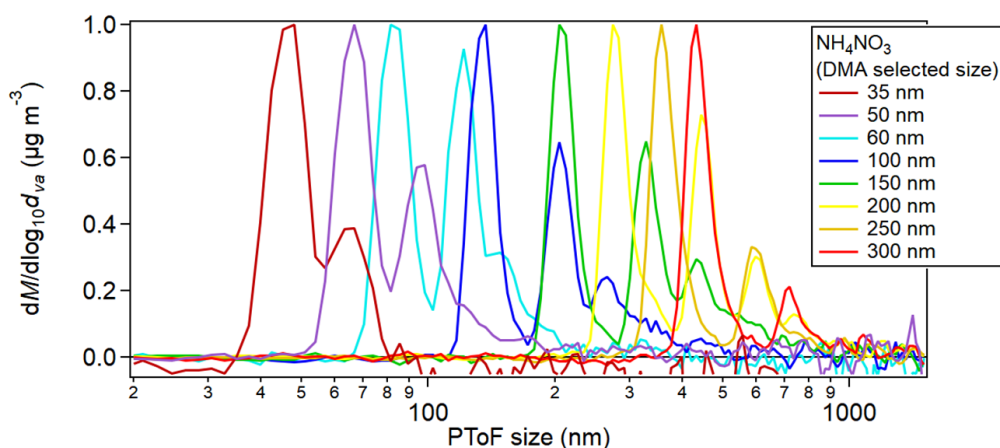

It is challenging to generate small monodisperse particles with the typical combination of a nebulizer and DMA-impactor system (TSI Inc.) which is not suitable for removing multiply charged particles below 150 nm  $d_m$  range. An evaporation-condensation system was used instead to generate monodisperse oleic acid particles for the characterization of the transmission efficiency in the 30-300 nm  $d_{va}$  range with minimal interference from multiply charged particles. Briefly, Zero Air (ZA) flows into a hot glass bulb containing oleic acid and then carries oleic acid vapor (heated flow). Evaporated oleic acid vapor inside the heated bath is mixed with zero air (quenching flow) via a glass “Y” and quenched going through a mixing tube, resulting in condensation of oleic acid and particle formation and growth (Fig. S1a). In the system used in this study, an additional heater was added to the evaporation-condensation system used by Krechmer et al. (2017) and Hu et al. (2018b) to fully encapsulate the glass bulb for homogeneous heating and minimize perturbations by temperature variations in the laboratory. The heat/quenching flows and the temperature of the heat bath determine the particle size distribution of oleic acid downstream of the evaporation-condensation system. The flows and temperatures were optimized for particle generation below 300 nm  $d_m$  by monitoring the particle size distribution using a scanning mobility particle sizer (SMPS) (Fig. S1b). Then the differential mobility analyzer (DMA) downstream of the small particle generator was used to select a particle size (larger than the peak diameter of the monomodal distribution) to minimize the population of doubly charged particles in the output (Fig. S1c). The monodispersity of the particle size distribution downstream of the DMA was routinely confirmed using AMS ePToF measurements (Fig. S2).

**Figure S1.1:** (a) Evaporation-condensation system modified for small particle generation. (b) Oleic acid volume size distributions measured by SMPS generated from the evaporation-condensation system at different temperatures, heat flow, and quenching flow setups. Although the system's response to temperature and flows was highly nonlinear, higher temperature and lower heat flow yielded larger particles. The selected DMA sizes were larger than the peak diameter to minimize the population of doubly charged particles (c).

**Figure S1.2.** (a) Particle size distributions of the monodisperse oleic acid particles measured by ePToF (dotted lines). The diameters denoted above the distributions are the mobility diameters selected by the DMA. The mean ePToF  $d_{va}$  was determined by fitting with the Gaussian function (solid line). The fitting range was selected so that fitting the tailing on the right shoulder is avoided. The tailing effect is due to the prolonged evaporation especially when the input aerosol concentration is high. (b) The nominal  $d_{va}$  ( $d_m \cdot \rho_{oleic\ acid} / \rho_{water}$ ) vs measured  $d_{va}$  using ePToF of the monodisperse oleic acid particles.  $\rho_{oleic\ acid} / \rho_{water}$  is 0.895. These are the data used for ePToF calibration of the PM<sub>1</sub> lens in Fig. 14d.

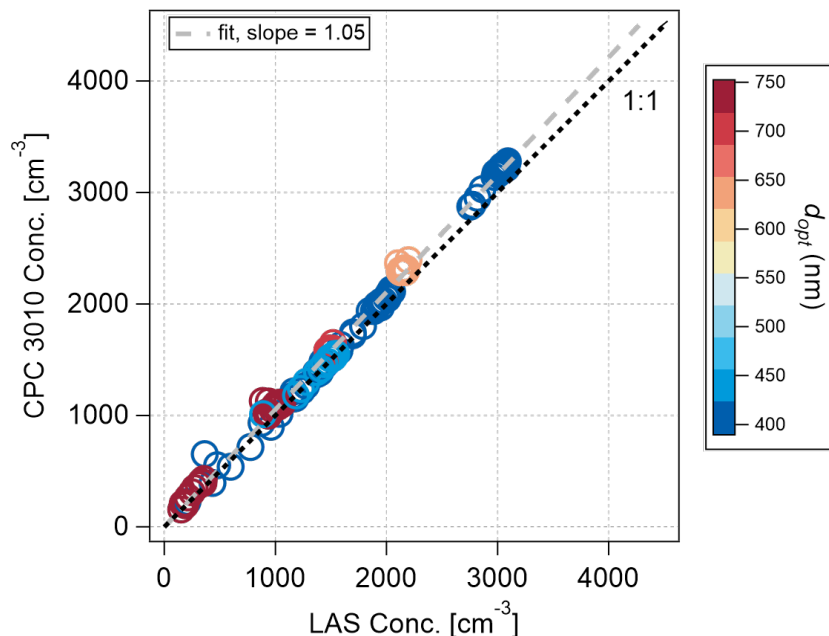

**Figure S1.3.** AMS PToF distribution of NH<sub>4</sub>NO<sub>3</sub> particles used for monodisperse BWP in Fig. 9. These were generated with a TSI atomizer and DMA without an impactor, hence multiply charged particles were present.

## S2. Measurement of CPC dilution factor

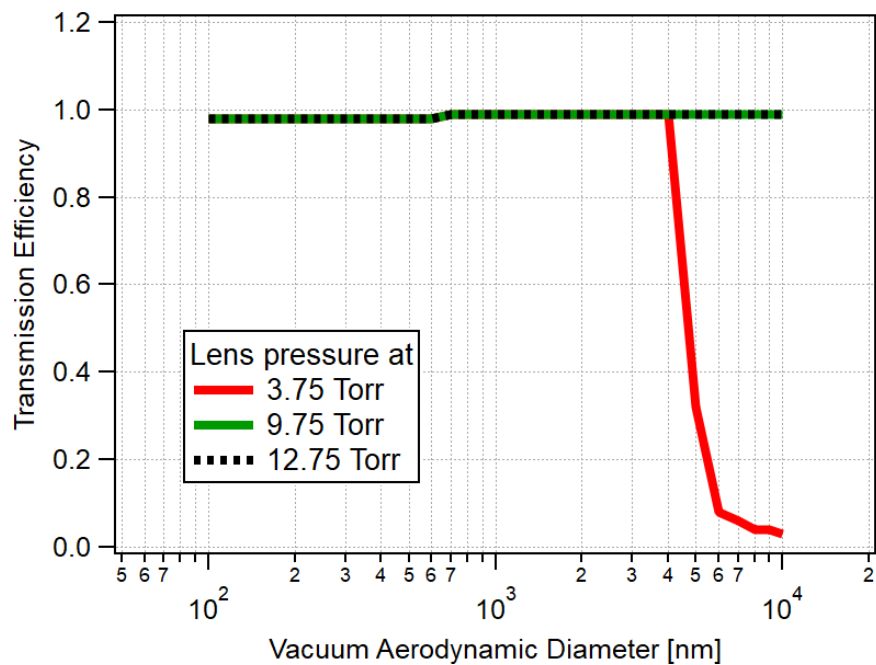

**Figure S2.1.** An example of particle dilution factor measurement of the particle dilution system in front of CPC 3010 (Fig.1) using 105 nm  $d_m$  oleic acid particles. The gray area indicates the measured particle counts while the dilution system is turned on and off. The red dots and markers are the particle concentrations without dilution and the blue dots and markers are particle counts multiplied by the dilution factor (26.5) during particle dilution. The dilution factor is the scaling factor applied to the diluted particle counts to match the undiluted particle counts. Measured dilution ratios were within the 25-27 range.

### S3. Particle loss in the sampling lines upstream of ADL

**Figure S3.1.** Scatter plot of particle concentrations from CPC 3010 and Laser aerosol spectrometer (LAS, TSI Inc.) using multiple PSL sizes. The data are colored by the optical diameter measured by the LAS. This comparison was performed to assess the particle losses in the sampling/dilution line between the AMS inlet and the CPC. The LAS was teed into the AMS inlet line (Fig. 1). If there were significant particle losses in the sampling line to the CPC, the losses of large particles would be more pronounced due to higher impaction losses. The absence of a systematic low bias for the CPC counts (especially the larger particles) indicates that the particle losses in the sampling line between CPC and AMS are negligible for submicron particles.

**Figure S3.2.** CFD modeling of particle transmission efficiency of the expansion volume version C (EV-C) with 120 μm critical

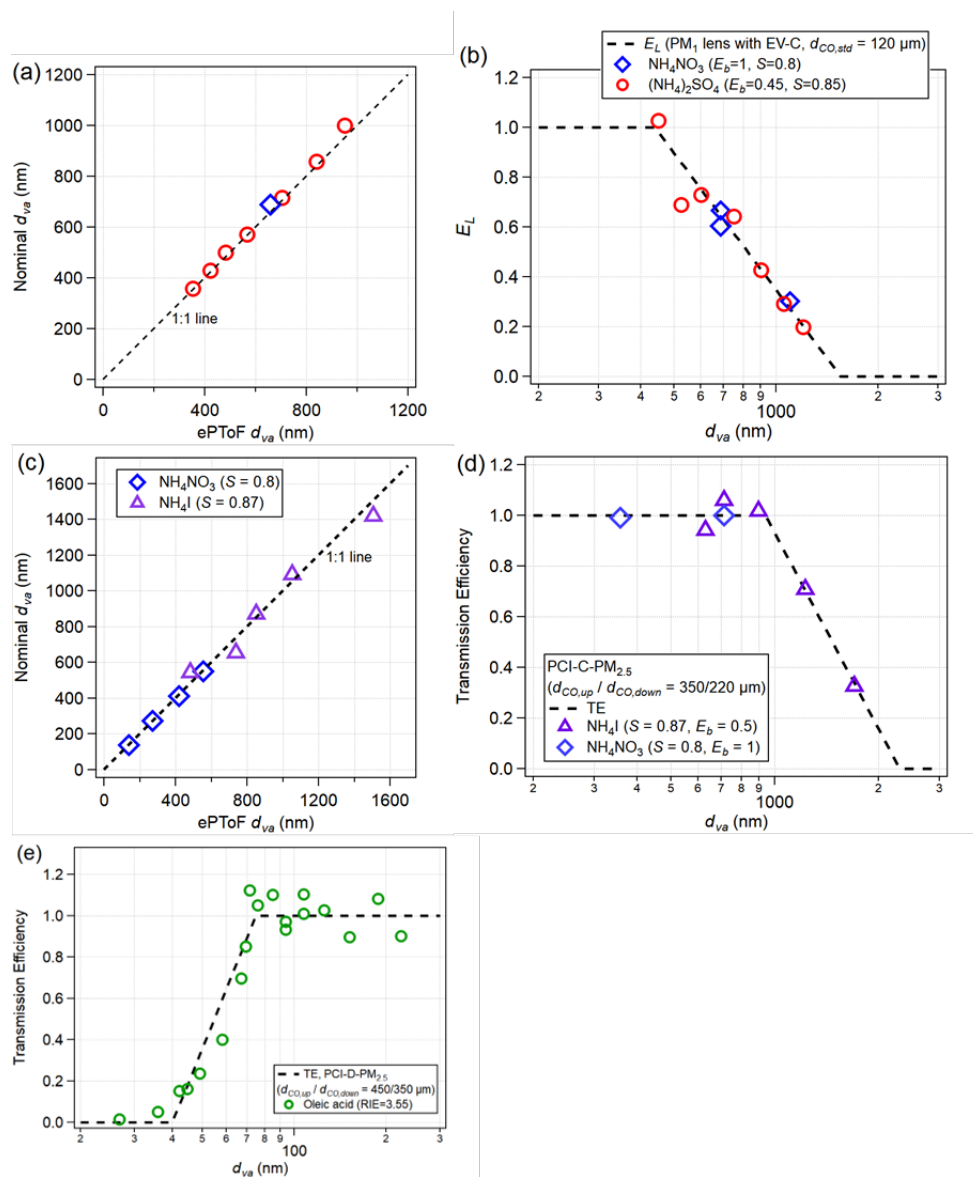

110 orifice.

#### S4. Determination of the Jayne shape factor ( $S$ ), $E_b$ , and RIE of test aerosols

In this study, oleic acid,  $\text{NH}_4\text{NO}_3$ ,  $(\text{NH}_4)_2\text{SO}_4$ , and  $\text{NH}_4\text{I}$  were used to measure inlet transmission efficiencies. Quantification of  $\text{NH}_4\text{NO}_3$  particles, extensively used for ionization efficiency calibration of AMS, is straightforward since it fully evaporates on the surface of the vaporizer without bouncing ( $E_b = 1$ ). The Jayne shape factor ( $S$ ) of  $\text{NH}_4\text{NO}_3$  is known to be 0.8 (Jayne et al., 2000). Thus, the transmission measurements with  $\text{NH}_4\text{NO}_3$  particles serve as reference and the parameters for quantification of other test aerosols ( $S$ ,  $E_b$ ) were derived in comparison to the measurements with  $\text{NH}_4\text{NO}_3$  and listed in Table S4.1.  $S$  of  $\text{NH}_4\text{I}$  and  $(\text{NH}_4)_2\text{SO}_4$  were determined by comparing with the measured  $d_{va}$  by AMS (ePToF  $d_{va}$ ) following Eq. 5 (Fig. S4.1a and c).  $1/E_b$  of  $\text{NH}_4\text{I}$  and  $(\text{NH}_4)_2\text{SO}_4$  is the scaling factor applied to match the transmission efficiency with  $\text{NH}_4\text{I}$  and  $(\text{NH}_4)_2\text{SO}_4$  to the transmission efficiency measured with  $\text{NH}_4\text{NO}_3$  (Fig. S4.1b and d). RIEs of  $\text{I}^-$  and  $\text{SO}_4^{2-}$  were measured relative to  $\text{NH}_4^+$ .  $E_b$  of oleic acid is 1 (Alfarra, 2004; Matthew et al., 2008). RIE of oleic acid is assigned so that the transmission efficiency is  $\sim 1$  over the  $d_{va}$  range where  $E_L$  or  $TE = 1$  (Fig. S4.1e). The measured values of  $E_b$ , RIE, and  $S$  in this work are summarized in Table S4.1 and Fig. S4.2. The measured RIE of oleic acid ( $3.58 \pm 0.39$ ) is within previously reported values, 3.0 (Xu et al., 2018),  $3.18 \pm 0.95$  (Katz et al., 2021), and 3.94 (Nault et al., 2023).

125

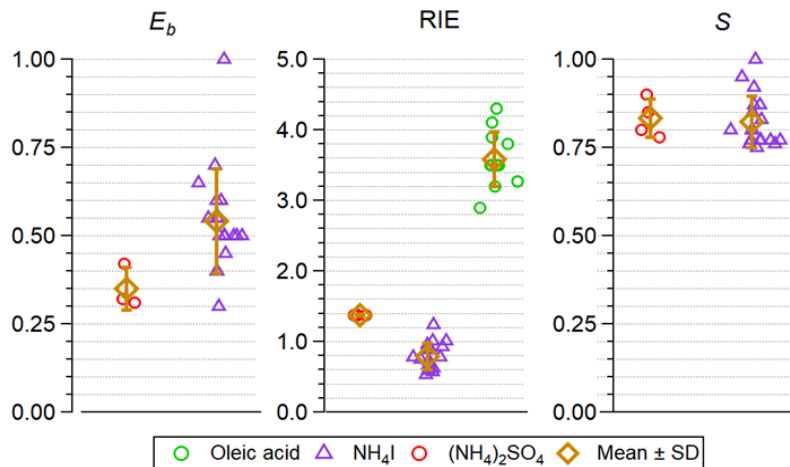

**Figure S4.1.** Examples of determination of the bouncing term of transmission efficiency ( $E_b$ ), Jayne shape factor ( $S$ ), and relative ionization efficiency (RIE) of the test aerosols. (a) Zoomed-in Fig. 14a on the large particle transmission and the data points are specified by the components. (b) The  $E_b$  of  $(\text{NH}_4)_2\text{SO}_4$  particles were determined by scaling to the  $\text{NH}_4\text{NO}_3$  particles. This specific case showed higher  $E_b$  for  $(\text{NH}_4)_2\text{SO}_4$  than normal values (Fig. S4.2). (c)  $S$  of  $\text{NH}_4\text{I}$  was determined by measuring the  $d_{va}$  of test aerosols with ePToF and comparing them with the nominal  $d_{va}$  ( $=$  bulk density ( $\rho_{\text{bulk}}$ ) $\cdot d_m \cdot S$ ). (d) The  $E_b$  of  $\text{NH}_4\text{I}$  was determined using the same method as in (b). (e) Determination of oleic acid RIE. The application of  $\text{RIE}_{\text{oleic acid}} = 3.55$  achieved the plateau at  $\text{TE} \sim 1$  over  $d_{va} > 80$  nm which is considered beyond the partial transmission region.

130

135 **Table S4.1.** The bulk density ( $\rho_{bulk}$ ), Jayne shape factor ( $S$ ), collection efficiency that accounts for particle bouncing at the  
vaporizer ( $E_b$ ), and relative ionization efficiency (RIE) of test aerosols. The  $E_b$  and RIE of PSL were not investigated because  
PSL was only used for PToF particle size calibration purposes where  $E_b$  and RIE are not needed. The RIE of  $\text{NH}_4^+$  is determined  
by comparison of  $\text{NO}_3^-$  mass in  $\text{NH}_4\text{NO}_3$  particles. Once the RIE of  $\text{NH}_4$  is determined, RIEs of  $\text{I}^-$  and  $\text{SO}_4^{2-}$  are determined by  
comparing to  $\text{NH}_4^+$  mass in  $\text{NH}_4\text{I}$  and  $(\text{NH}_4)_2\text{SO}_4$  particles. Error bars indicate the standard deviation of measured values.  $E_b$   
140 of dry  $(\text{NH}_4)_2\text{SO}_4$  particles reported in this study is consistent with other studies, e.g., 0.25–0.5 (2008), 0.4–0.5 (Hu et al.,  
2017) and  $0.37 \pm 0.13$  (Day et al., 2022). Note that  $S$  of dry  $(\text{NH}_4)_2\text{SO}_4$  particles is typically assumed to be 1 when estimating  
 $E_b$  from mass based comparison between AMS and CPC, in which case the reported  $E_b$  is  $E_b \cdot S$ . In this study,  $S$  was measured  
with from ePToF (Fig. S4.1) and applied to Eq. 10 when estimating  $E_b$  from AMS and CPC mass comparison.

Compound	$\rho_{bulk}$ ( $\text{g cm}^{-3}$ )	$S$	$E_b$	RIE
PSL	1.055	1	-	-
Oleic acid	0.895	1	1	$3.58 \pm 0.39$ (OA*)
$\text{NH}_4\text{NO}_3$	1.72	0.8	1	-
$(\text{NH}_4)_2\text{SO}_4$	1.77	$0.83 \pm 0.05$	$0.35 \pm 0.06^*$	$1.38 \pm 0.01$ ( $\text{SO}_4^{2-}$ )
$\text{NH}_4\text{I}$	2.51	$0.82 \pm 0.07$	$0.54 \pm 0.15$	$0.79 \pm 0.19$ (I <sup>-</sup> )

145

**Figure S4.2.** The  $E_b$  RIE and  $S$  data are measured with three ADLs ( $\text{PM}_{10}$ ,  $\text{PM}_{2.5}$  lens, and HPL), with and without PCI, and with two standard vaporizers. The mean values  $\pm$  standard deviation are listed in Table S4.1.

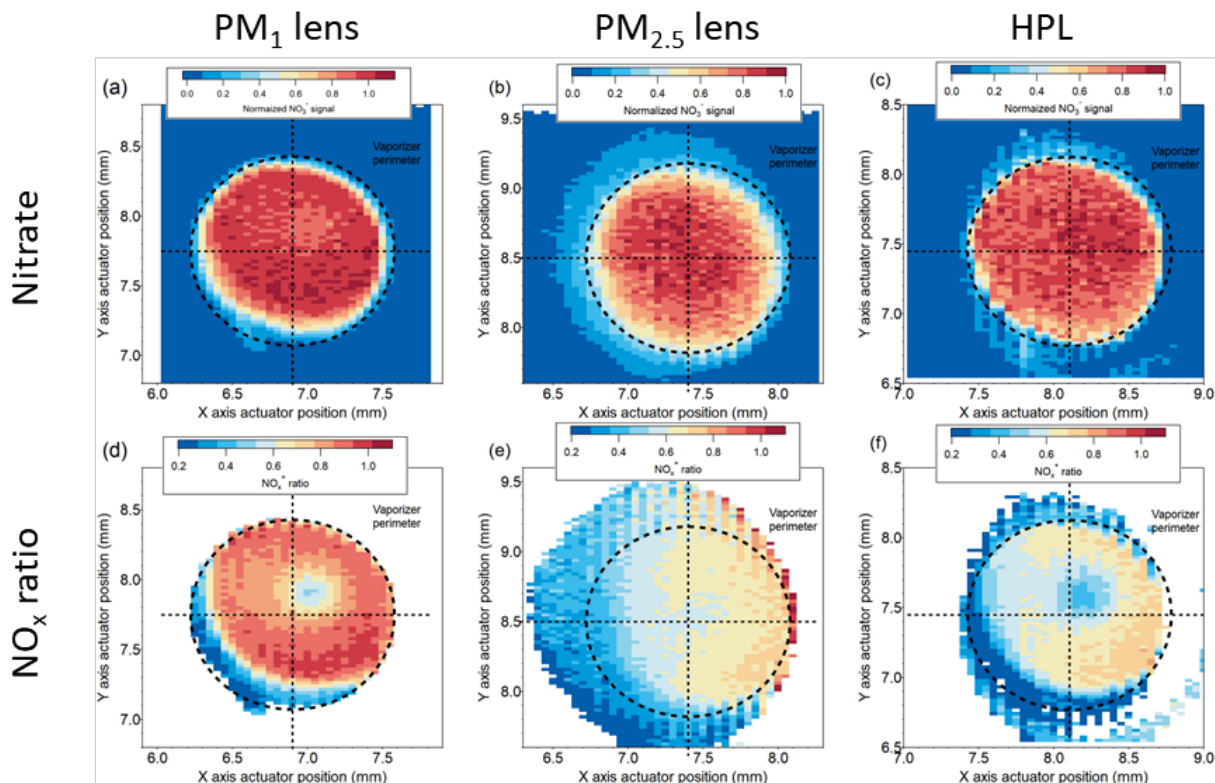

150 **Figure S4.3.** Gaussian fitting of inorganic species for ePToF  $d_{va}$  measurements. Volatile inorganic species ( $\text{NH}_4\text{NO}_3$ ) were fitted with a full data range. The less/non-volatile inorganic species ( $\text{NH}_4\text{I}$  and  $(\text{NH}_4)_2\text{SO}_4$ ) were fitted up to a few measurement points beyond the peak (thick red line) so as not to include the broadening on the right shoulder. The right shoulder is an indication of delayed evaporation of less/non-volatile particles on the vaporizer (Drewnick et al., 2015) and thus excluded in the fitting to minimize the potential overestimation of particle size. The measurement of ePToF  $d_{va}$  is used to estimate the

155 Jayne shape factor ( $S$ ) which enters into the conversion of  $d_{mob}$  to  $d_{va}$  and the calculation of particle mass (Eq. 5 and Eq. 10).

## S5. 2D Lens scan stage details and results

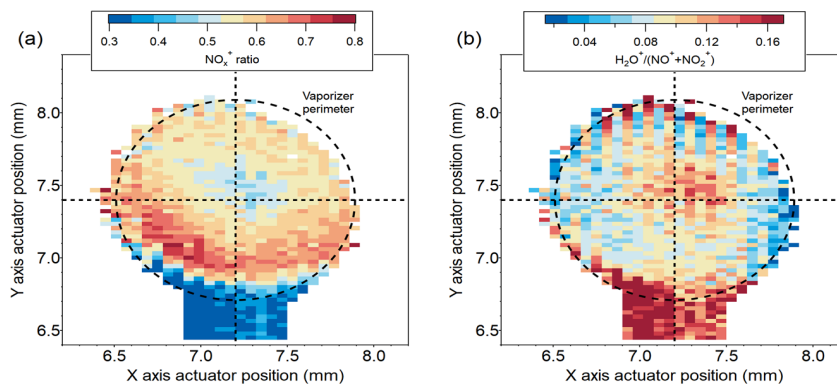

160 **Figure S5.1.** Picture of the 2D lens scan stage assembly shown in Fig 3. During operation, the electronic actuator pushes the  
ADL, changing the aerosol beam direction as its pivot is fixed. During a lens scan, the Y actuator sweeps each leg at  $0.05 \text{ mm s}^{-1}$ ,  
and then at the end of each Y sweep, the X actuator moves  $0.1 \text{ mm}$  (Fig. 6). The length from the actuator to the end of  
ADL is  $0.138 \text{ m}$  and the length from the end of ADL (pivot) to the vaporizer is  $0.348 \text{ m}$ . Thus the displacement of the aerosol  
beam position at the vaporizer plane is equal to  $-2.65$  (negative sign means the actuator direction and beam movement direction  
165 are opposite due to the pivot) times the displacement of the actuator.

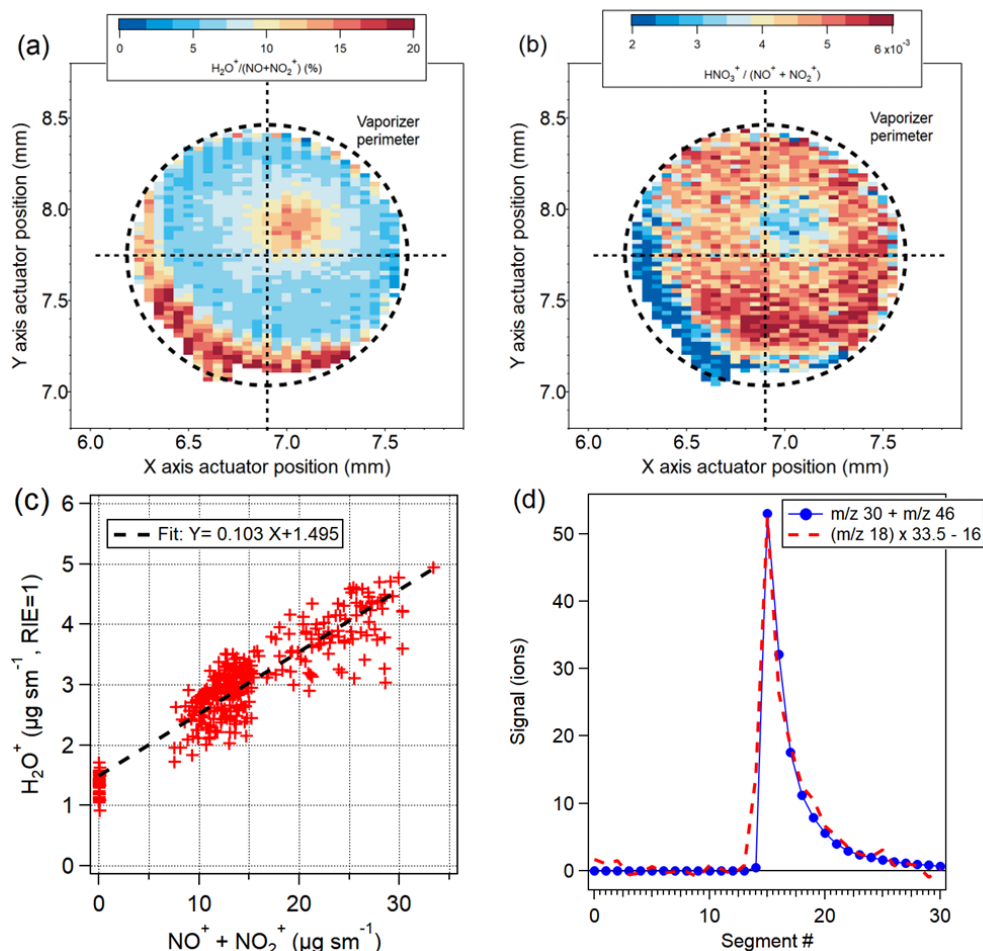

**Figure S5.2.** Lens scan results from the  $\text{PM}_1$  lens,  $\text{PM}_{2.5}$  lens, and HPL (left, middle, right column) in Fig. 7. The top row shows the particle signals normalized by particle concentration, and the bottom row shows the vaporizer position-dependent

170  $\text{NO}_x^+$  ratios.

**Figure S5.3.** (a)  $\text{NO}_x$  ratio and  $\text{H}_2\text{O}^+ / (\text{NO}^+ + \text{NO}_2^+)$  from lens scan with a new, not tilted, standard vaporizer used for the  $\text{TI}^3\text{GER}$  campaign. These results are from the  $\text{PM}_{2.5}$  lens and 500 nm  $d_m$   $\text{NH}_4\text{NO}_3$  particles. The new standard vaporizer shows a lower

175  $\text{NO}_x$  ratio at the vaporizer center. This confirms that the results and conclusions made with lens scans in this work are not specific to the vaporizer used here and, thus, can be applied to standard vaporizers in general.

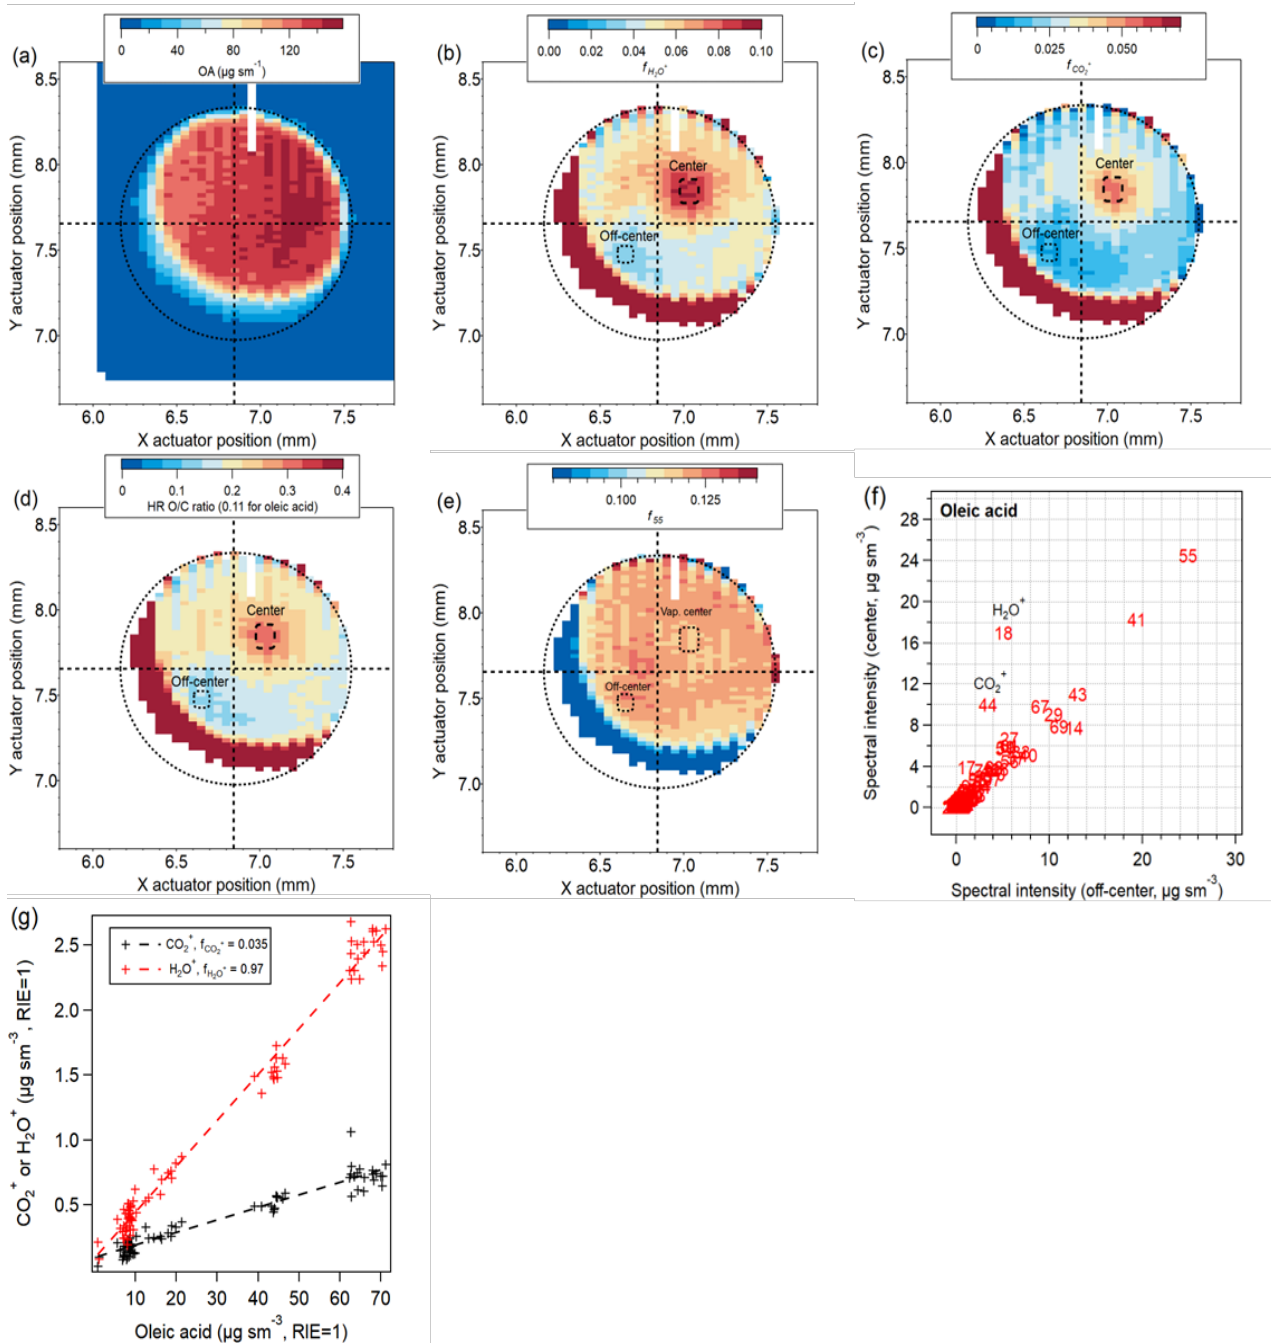

**Figure S5.4.** Lens scan results are shown for (a)  $\text{H}_2\text{O}^+/\text{NO}_x^+$  and (b)  $\text{HNO}_3^+/\text{NO}_x^+$ . (a) and (b) are results from the same lens scan as Fig. S5.2a. Near the vaporizer center, the  $\text{H}_2\text{O}^+$  signal was  $\sim 10\%$  of major nitrate fragments, similar to the MS mode case. At the center of the vaporizer, the fraction increases up to 14-15%. Although noisier than (a), (b) shows a decrease in the  $\text{HNO}_3^+$  signal at the center of SV due to higher thermal decomposition of  $\text{NH}_4\text{NO}_3$ . Compared to off-center positions,  $\sim 25\%$  of the signal drop was observed. (c) Scatter plot of  $\text{H}_2\text{O}^+$  and  $\text{NO}_x^+$  taken in bulk MS mode using fast mode acquisition. (d) Comparison of nitrate signal (m/z 30 and 46 that correspond to  $\text{NO}^+$  and  $\text{NO}_2^+$  ions) and water signal (m/z 18 that corresponds to  $\text{H}_2\text{O}^+$ ) after background subtraction during event trigger (ET) mode with 500 nm  $d_m$   $\text{NH}_4\text{NO}_3$  particles. The ion signal is recorded once a single particle is detected. The  $\text{H}_2\text{O}^+$  signal during ET mode was  $\sim 3\%$  of major nitrate fragmentation ions. The same aerosol source was used for (c) and (d). ET mode and MS mode were alternated 3 times. In fast mode, the  $\text{H}_2\text{O}^+$  signal was  $\sim 10\%$  of major nitrate fragments.

**Figure S5.5.** (Top)  $\text{NH}_3^+/\text{NH}_2^+$  and (Bottom) normalized nitrate mass, ammonium mass, and their ratio from  $\text{NH}_4\text{NO}_3$  particles as a function of  $\text{NO}_x^+$  ratio ( $\text{NO}_2^+/\text{NO}^+$ ) on a standard vaporizer (SV) and capture vaporizer (CV). In the bottom plot, SV values were normalized by the values at the SV center positions ( $\text{NO}_x^+$  ratio  $\sim 0.5\text{--}0.65$ ). Outside of the CV (on the edge of the entrance), the  $\text{NO}_x^+$  ratio was comparable to that of off-center positions on SV. CV values were normalized to match the SV values at the CV edge  $\text{NO}_x^+$  ratio ( $0.8\text{--}0.85$ ). The CV data was adopted from Hu et al. (2017). Nitrate to ammonium ratio was used to track the nitrate sensitivity due to thermal decomposition (indicated by  $\text{NO}_x^+$  ratio). Thermal decomposition if ammonium was constant (as indicated by the  $\text{NH}_3^+/\text{NH}_2^+$  fragmentation ratio) and thus there is negligible variance in the species of gases ionized after evaporation. However, ammonium mass was  $\sim 10\%$  lower at the SV center compared to SV off-center positions for unidentified factors, other than thermal decomposition. Therefore, nitrate was normalized by ammonium

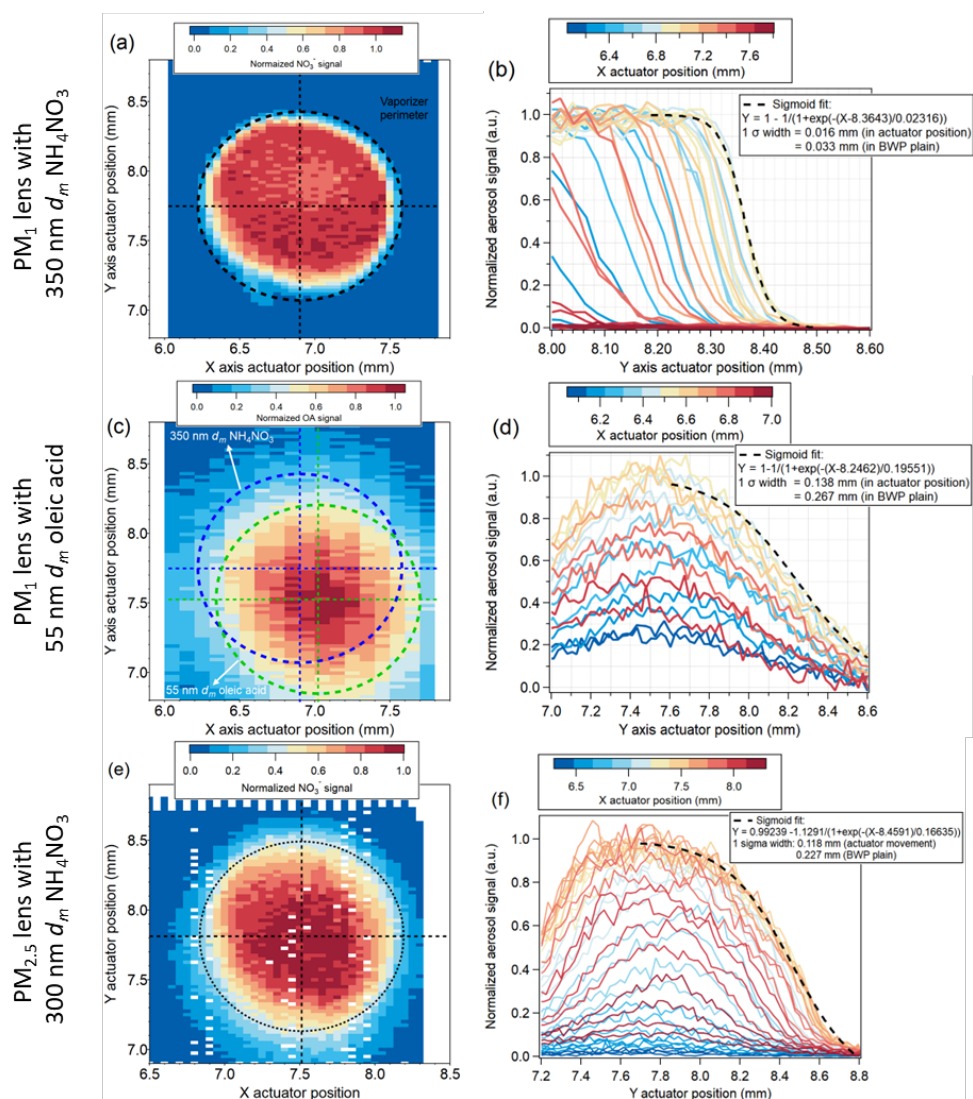

in this analysis, to minimize the influence from these unidentified factors. Inside the CV cavity, the  $\text{NO}_x^+$  ratio was below 0.1 due to the significant thermal decomposition of  $\text{HNO}_3(\text{g})$ . The nitrate/ammonium ratio was  $\sim 7\text{--}10\%$  lower than the CV edge than SV (assuming that this is not driven by the losses of nitrogen oxides inside the cavity). On the SV center, the ratio was  $\sim 3\%$  lower than off-center positions. This is probably because the ionized gases consist of less  $\text{HNO}_3(\text{g})$  and more  $\text{NO}_2(\text{g})$  and  $\text{NO}(\text{g})$  in case of more thermal decomposition of nitrate (lower  $\text{NO}_x^+$  ratio), such as inside the CV cavity and SV center.

205

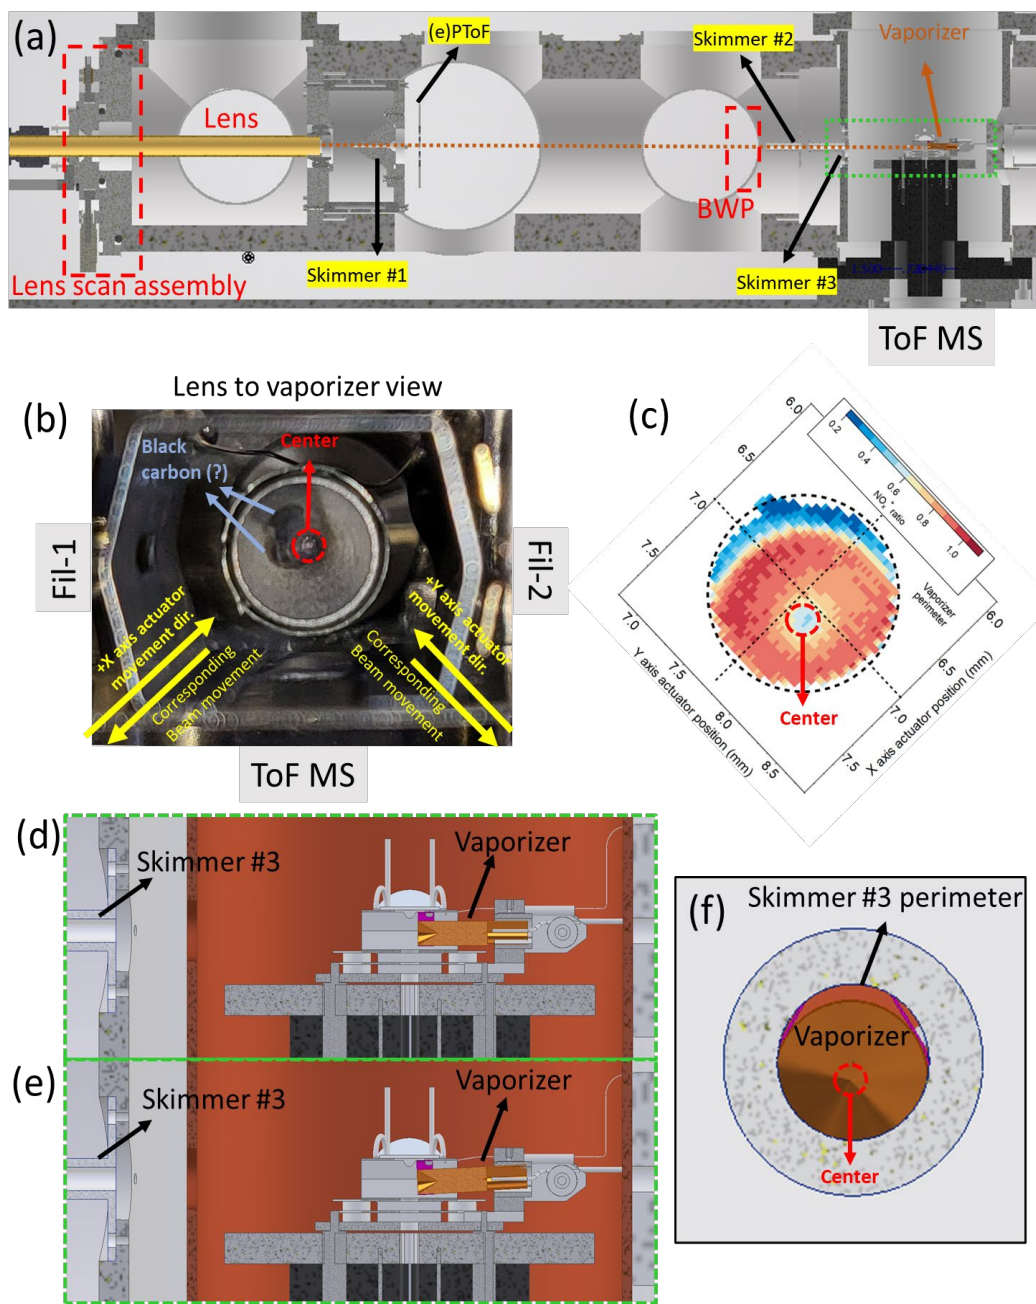

**Figure S5.6.** Lens scan results of (a) oleic acid mass concentration, (b)  $f_{\text{H}_2\text{O}^+}$ , (c)  $f_{\text{CO}_2^+}$ , (d) O/C atomic ratio, from  $\text{PM}_{10}$  lens and 260 nm  $d_m$  oleic acid particles, (e)  $f_{55}$ . (f) comparison of spectral intensity from oleic acid at the vaporizer center vs. off-center position. The O/C ratio was calculated using the  $f_{\text{CO}_2^+}$  parametrization from (Canagaratna et al., 2015). Similar to the  $\text{NH}_4\text{NO}_3$  case, oleic acid particles produce higher  $\text{H}_2\text{O}^+$  and  $\text{CO}_2^+$  when hitting the vaporizer center, indicating further

210 fragmentations. Higher  $\text{CO}_2^+$  results in both higher  $f_{44}$  and hence O/C estimation, up to  $\sim 6$  and 2 times higher, respectively,  
compared to the off-center position. This suggests that the organic  $\text{CO}_2^+$  signal may be affected by the particle beam position  
when measuring ambient organic aerosols, resulting in potentially some instrument to instrument variability in the reported  
O/C for less oxidized OA as shown in Crenn et al. (2015). Note that during this lens scan, the inlet was pulled by a plumbing  
line when actuator positions were low. While that resulted in a somewhat distorted lens scan image, it does not affect the  
215 results discussed here. (g) linearity between fragment signal ( $\text{H}_2\text{O}^+$  and  $\text{CO}_2^+$ ) and oleic acid mass at a fixed lens position. The  
 $\text{H}_2\text{O}^+/\text{CO}_2^+$  ratio from this study that used evaporation-condensation for oleic acid particle generation is  $\sim 2$  and Hu et al.  
(2018a) that used nebulization with hexane solvent was 2.1.

220 **Figure S5.7.** The left column shows lens scan results of the normalized signal of oleic acid or nitrate aerosol. The right column shows the normalized particle signal vs. Y axis actuator position colored by X actuator position during each lens scan. The first row shows lens scan results with the  $\text{PM}_{1.0}$  lens and  $350 \text{ nm } d_m \text{ NH}_4\text{NO}_3$  particles. The second row shows results with the  $\text{PM}_{1.0}$  lens and  $55 \text{ nm } d_m$  oleic acid particles. The third row shows results with the  $\text{PM}_{2.5}$  lens and  $300 \text{ nm } d_m \text{ NH}_4\text{NO}_3$  particles. The sigmoidal fit of the Y sweep when the X actuator position corresponds to the vaporizer center shows that the  $1 \sigma$  beam width of the  $\text{PM}_{1.0}$  lens can be as sharp as  $0.033 \text{ mm}$  in the BWP plane. The beam width measurement of  $55 \text{ nm } d_m$  oleic acid with lens scan is not reliable since the beam was too wide that a plateau regime across y actuator position was not obvious. However, the difference in beam center position was identified (Fig. 11b). The beam width of  $300 \text{ nm } d_m \text{ NH}_4\text{NO}_3$  particles was much wider than that from (b) which is consistent with BWP-based beam width measurements (Fig. 11a). More beam width measurements from lens scan are included in Fig. 11a.

225

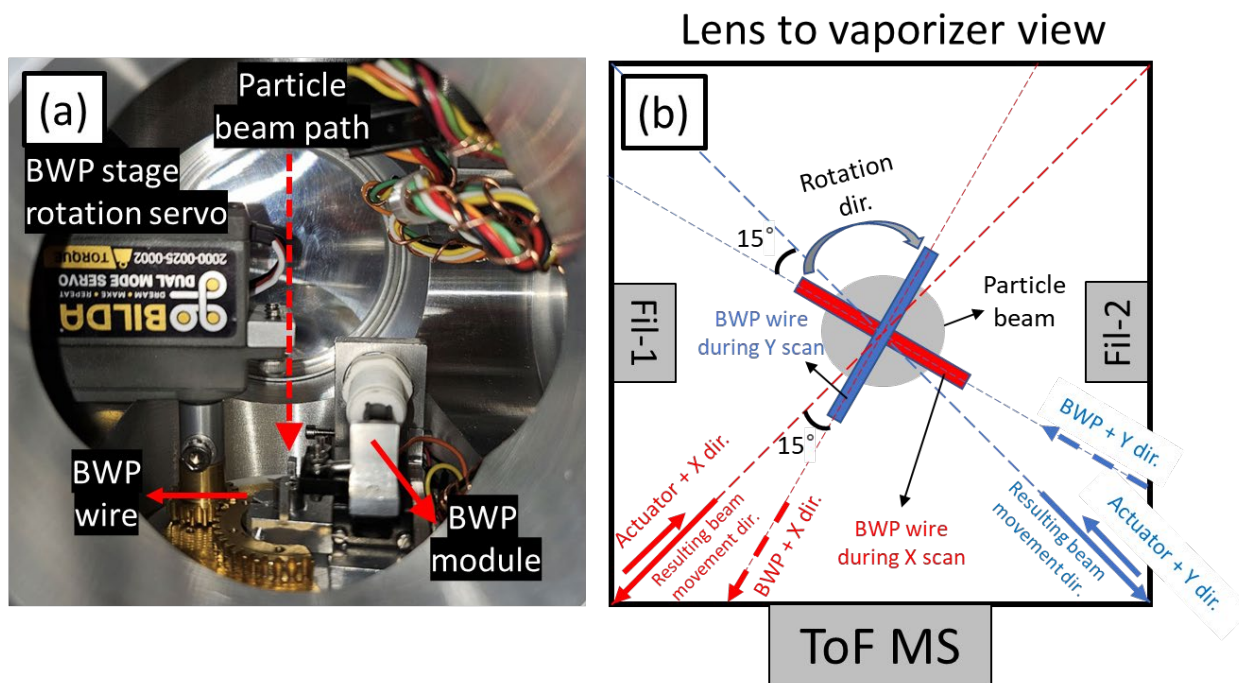

230

235

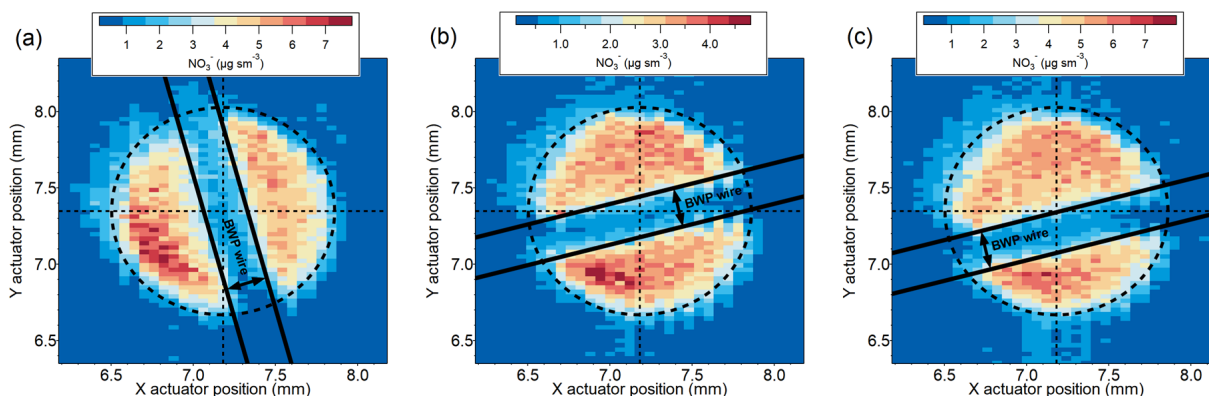

**Figure S5.8.** (a) Diagram of AMS cross section including the positions of skimmers and vaporizer. (b) Picture of the vaporizer used for all the lab characterizations of the different lenses shown above (which was replaced for the TP<sup>3</sup>GER campaign). (c) Lens scan with PM<sub>1</sub> lens and mapped by NO<sub>x</sub><sup>+</sup> ratio. Zoomed in figures of the green dotted box in (a) with different vaporizer misalignment cases: (d) the vaporizer with 0.45 mm higher location and (e) the vaporizer tilted 2.75 degrees downward. (f) Vaporizer blocked by the skimmer #3 as a result of vaporizer misalignments in (d) and (e). The position where the NO<sub>x</sub><sup>+</sup> ratio

is low (higher thermal decomposition) is likely the (projected) center of the vaporizer. The fact that the location of the physical center and the center the lens scan do not match indicates that the particle beam is hitting the vaporizer at a certain angle (up to ~3 degrees) and/or height of the vaporizer is misaligned (up to ~ 0.5 mm). The absence of ~60% vaporizer perimeter during lens scan suggests that the ~ 60% of the vaporizer edge was blocked by the third skimmer which implies that the skewed  $\text{NO}_x^+$  ratio image from lens scan could be more attributed to the translated vaporizer position.

## S6. BWP rotation stage and wire position measurement

245 **Figure S6.1.** (a) Picture of the Aerodyne BWP and the custom-built BWP rotation assembly. (b) Schematic diagram of BWP axes and lens scan actuator axes as aligned for the TI<sup>3</sup>GER mission (ideally the two coordinate systems are set on top of each other).

250

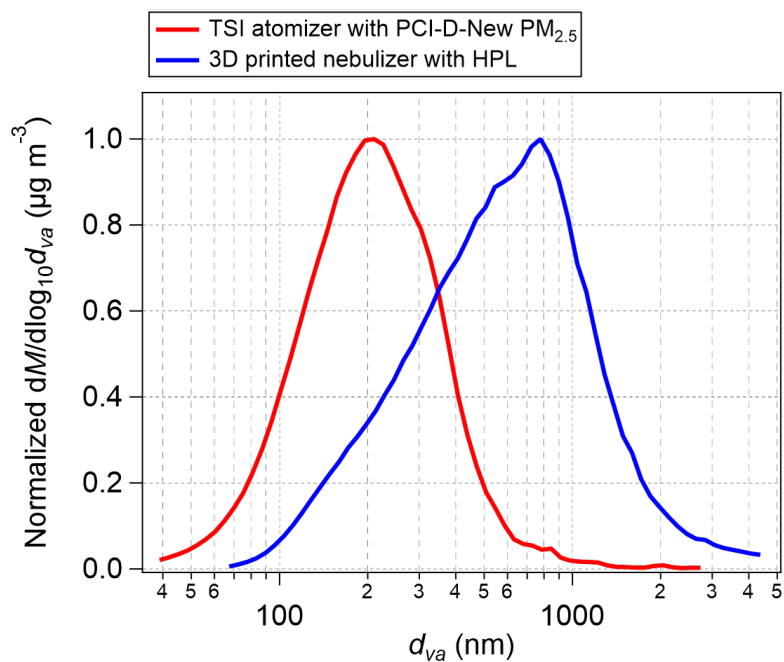

**Figure S6.2.** Lens scan imaging used to measure the offset of the BWP relative to the vaporizer coordinate system. Ideally, the zero BWP position is located on the line between the lens exit nozzle and the center of the vaporizer. The offset in BWP position can be attributed to many factors including the off-center vaporizer installation and the potential inherent offset in BWP hardware. The lens scan stage was run with the BWP wire parked at a certain position and the BWP was imaged to measure the BWP position relative to the vaporizer center. (a-c) shows the rotation of the beam wire (parked in the center position blocking the middle of the particle beam) while running a sweep with the lens scan, allowing to relate both coordinate systems to each other. Results of lens scans with the BWP wire parked along (a) X axis at +0.5 mm wire position (b) Y axis at +0.6 mm wire position (c) Y axis +0.8 mm wire position. We found that for the TI<sup>3</sup>GER configuration, the BWP wire set positions along the X and Y axes, +0.5 mm and +0.6 mm, correspond to the vaporizer center position in our setup. As illustrated in Fig. S6.1(b), BWP X and Y axes were 15 degrees off from the lens scan actuator X and Y axes. Notably, the BWP wire position difference between (b) and (c) measured by the lens scan is 0.198 mm which is close to the set wire position difference (0.2 mm). Lens scans were performed with 500 nm  $d_m$   $\text{NH}_4\text{NO}_3$  particles with  $\text{PM}_{2.5}$  lens.

255

260

## S7. Polydisperse particle generation for 2D-SR-BWP analysis

265

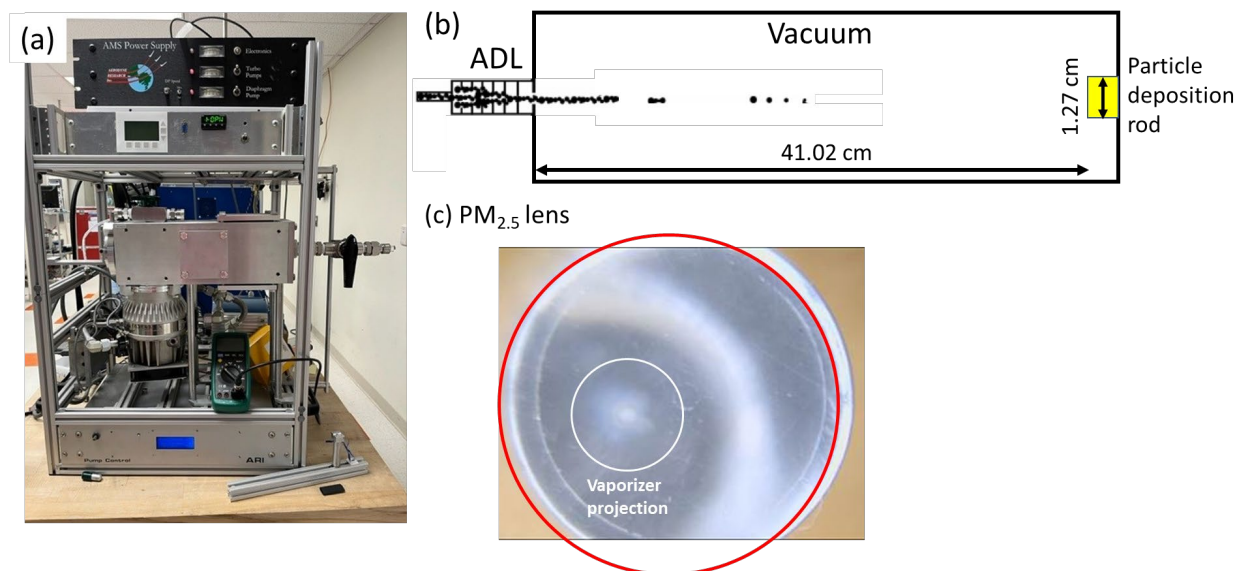

**Figure S7.1.** Mass size distribution of  $\text{NH}_4\text{NO}_3$  particles generated by the customized 3D printed nebulizer (blue) and TSI atomizer (model 3076, red).  $\text{NH}_4\text{NO}_3$  solutions of  $\sim 0.7$  M concentration were used. Most of the measured distributions were within  $\sim 100\%$  transmission efficiencies of the inlet used for each nebulizer. The nebulizers were operated at  $\sim 35$  psi nozzle pressure.

270

**Figure S7.2.** Reference size distributions and 1 sigma variability (%) of the regular, unperturbed PToF distributions during the scan along the X axis in Fig. 8.

## S8. Particle deposition image

275

**Figure S8.1.** (a) A picture of the particle deposition system. (b) Schematic diagram of the Aerodyne particle deposition system. (c) The original image of particle deposition tests and the vaporizer perimeter projection (white circles) on the deposition rod were measured with the PM<sub>2.5</sub> lens beam deposition image. The red solid circles are the perimeter of the particle deposition rod (12.7 mm diameter). Only the particle deposition images within the projected vaporizer perimeters are shown in Fig. 13.

280 The distance between the lens nozzle and rod distance is 0.4102 m. In the CU-HR-AMS system, the nozzle-to-vaporizer distance is 0.3545 m. Assuming radial expansion of the aerosol beam at the end of the nozzle, the projected vaporizer diameter-to-rod diameter ratio is 0.328.

## S9. Characterizations of standalone ADLs

285 **Table S9.1.** The approximate particle diameter range ( $E_L = 50\%$ ) of the aerodynamic lense transmission efficiency curves is shown in Fig. 14.

Aerodynamic lens type	Reference	$d_{va,50,low}$ (nm)	$d_{va,50,high}$ (nm)	$P_{lens}$ (mbar)	$d_{CO,std}$ ( $\mu\text{m}$ )
PM <sub>1</sub> lens	Zhang et al. (2004)	45	-	-	-
	Liu et al. (2007) <sup>a</sup>	63	900	-	-
	Liu et al. (2007) <sup>b</sup>	95	650	1.73	100
	Knote et al. (2011)	63	1060	-	-
	This work	47	830	2	120
PM <sub>2.5</sub> lens	Xu et al. (2017)	150	4000	5.1	-
	Molleker et al. (2020)	< 200	2600	-	100
	This work	55	2700	5.1	120
HPL	Williams et al. (2013)	85	> 3000	18.4	100
	This work	120	> 1500	21	120

<sup>a</sup>at 780 mbar ambient pressure. <sup>b</sup>at 1013 mbar ambient pressure.

**Table S9.2.** The trapezoid curves in Fig. 14. consist of: – 0 % transmission below  $d_{va,0,low}$ ; – linear increase in transmission vs  $\log(d_{va})$ , from 0 % at  $d_{va,0,low}$  to 100 % at  $d_{va,100,low}$ ; – 100 % transmission from  $d_{va,100,low}$  up to  $d_{va,100,high}$ ; – linear decrease in transmission vs  $\log(d_{va})$ , from 100% at  $d_{va,100,low}$  to 0 % at  $d_{va,0,high}$ .

ADL	$d_{va,0,low}$ (nm)	$d_{va,100,low}$ (nm)	$d_{va,100,high}$ (nm)	$d_{va,0,high}$ (nm)
PM <sub>1</sub> lens	34	64	440	1550
PM <sub>2.5</sub> lens	36	82	1500	5000
HPL	85	170	> 1500	> 1500

**Table S9.3.** This table shows the ePToF parameters applied to derive Fig 14(d). The  $v_l$  values for PM<sub>2.5</sub> lens and HPL were adopted from Xu et al. (2017) and Williams et al. (2013), respectively. The  $v_g$  values were measured by AMS PToF. The  $D_b$  and  $b$  values were fitted by Eq. 4.

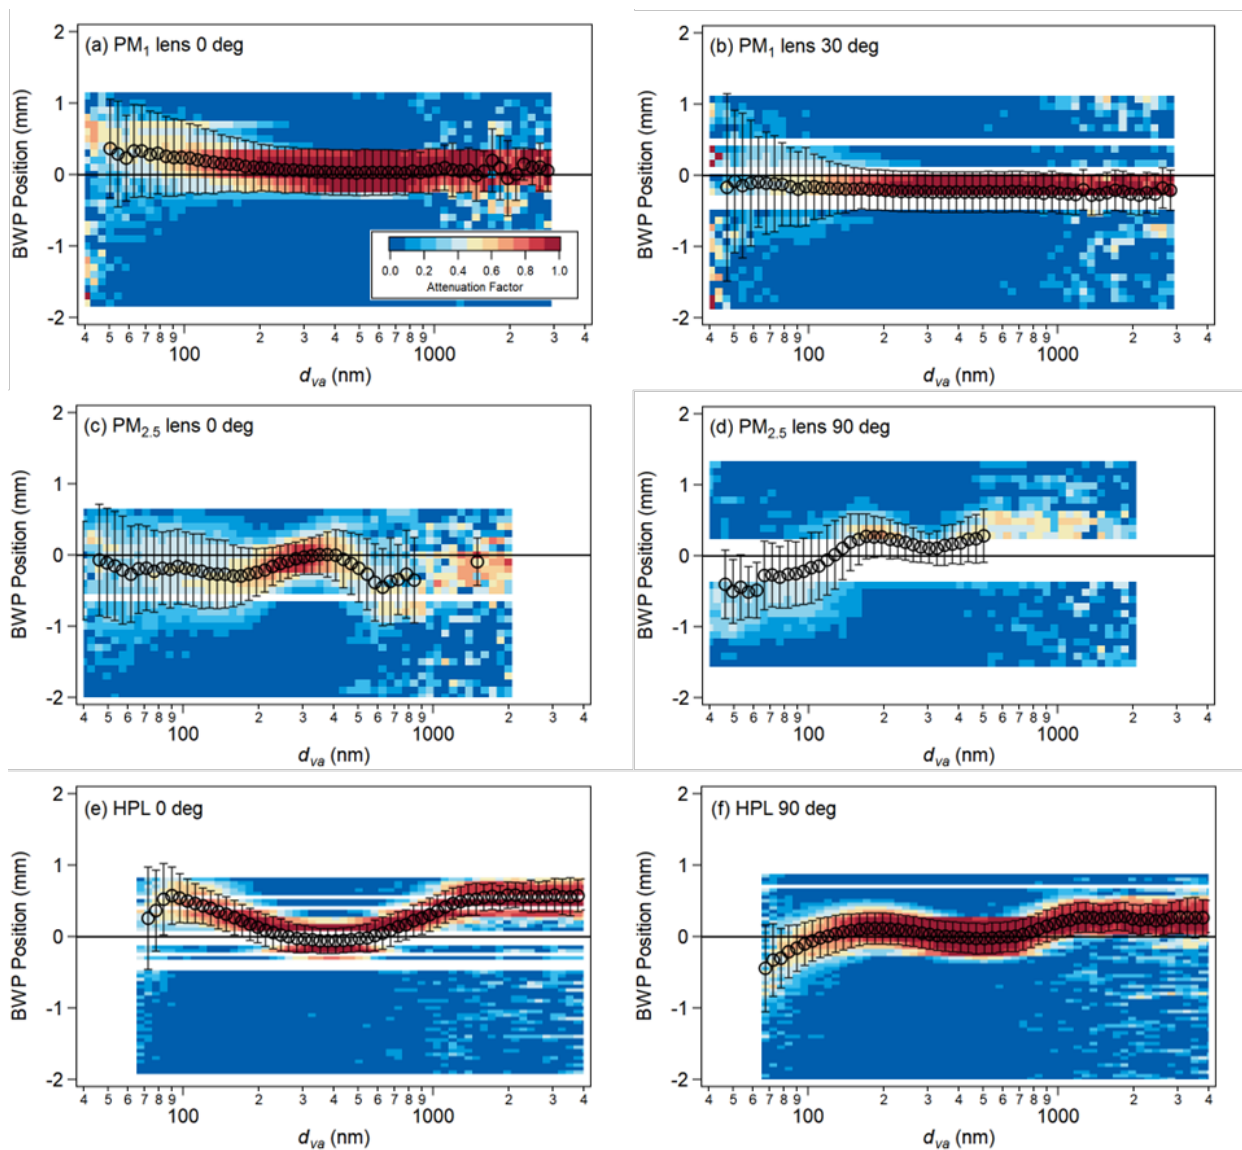

ADL	$P_{Lens}$ (mbar)	$v_g$ (m s <sup>-1</sup> )	$v_l$ (m s <sup>-1</sup> )	$D_b$ (nm)	$b$ (unitless)
PM <sub>1</sub> lens	2	746.14	15	4.7305	0.43836
PM <sub>2.5</sub> lens	5.1	702	15.59	13.045	0.46917
HPL	21	746.1	78.50	30.321	0.73314

**Table S9.4.** Measured  $E_L$  of PM<sub>1</sub>, PM<sub>2.5</sub> lens, and HPL shown in Fig. 14.

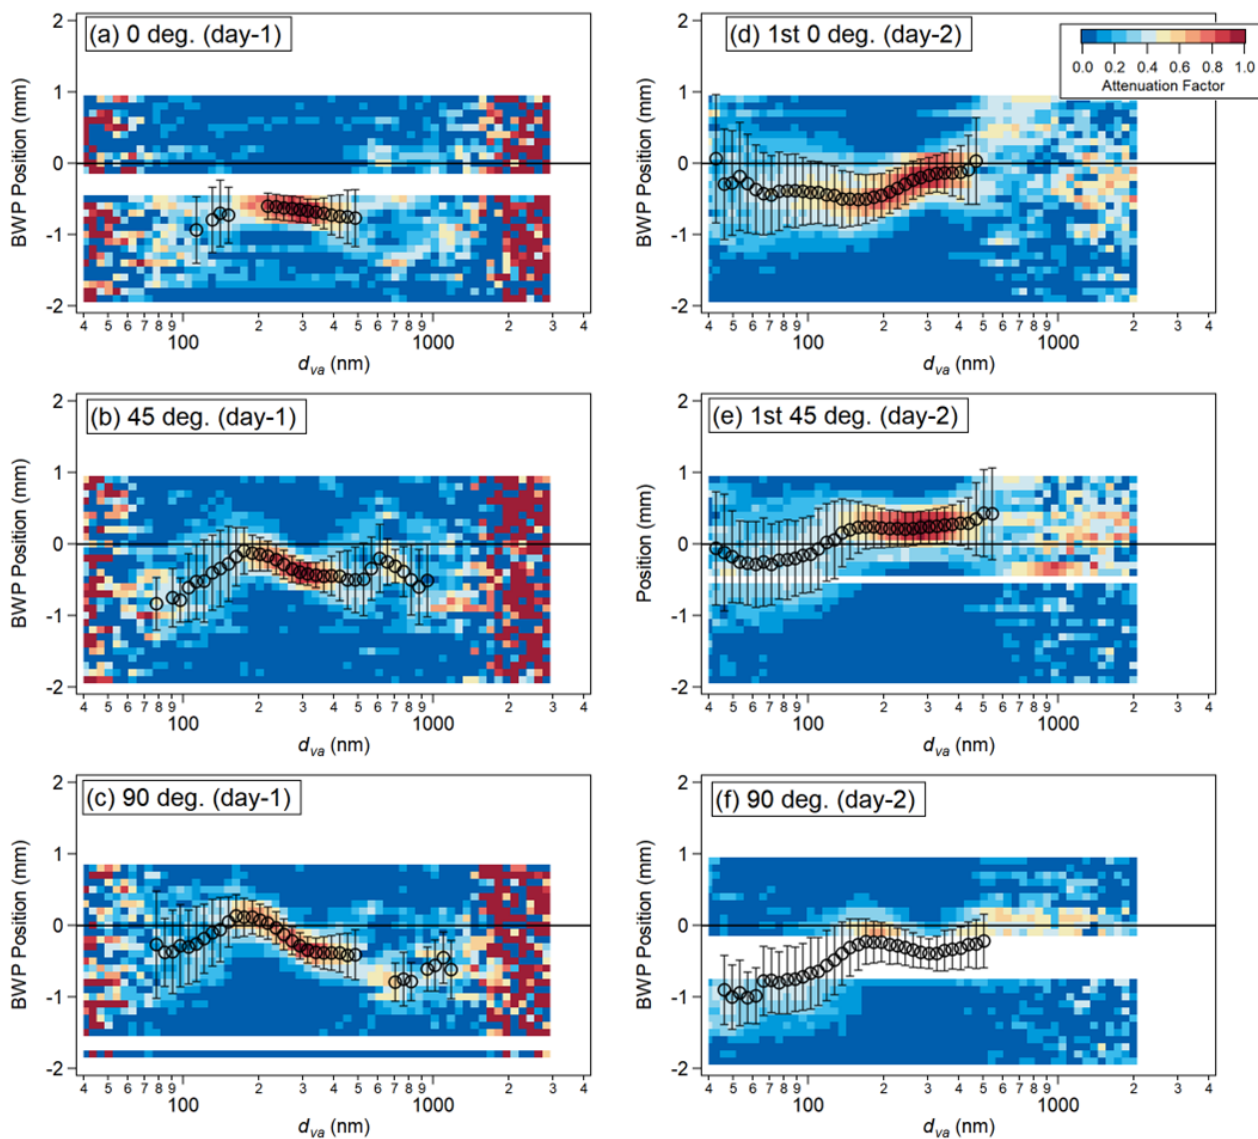

PM <sub>1</sub> lens			PM <sub>2.5</sub> lens			HPL

<sup>a</sup>RIE = 3.5. <sup>b</sup> $S = 0.85$ ,  $E_b = 0.43$ . <sup>c</sup>RIE = 3.5. <sup>d</sup> $S = 1$ ,  $E_b = 0.55$ . <sup>e</sup>RIE = 3.04. <sup>f</sup> $S = 0.87$ ,  $E_b = 0.32$ .  $S$  and  $E_b$  of NH<sub>4</sub>NO<sub>3</sub> are 0.8 and 1 for all the transmission measurements.

## S10. 2D-SR-BWP results from ADLs

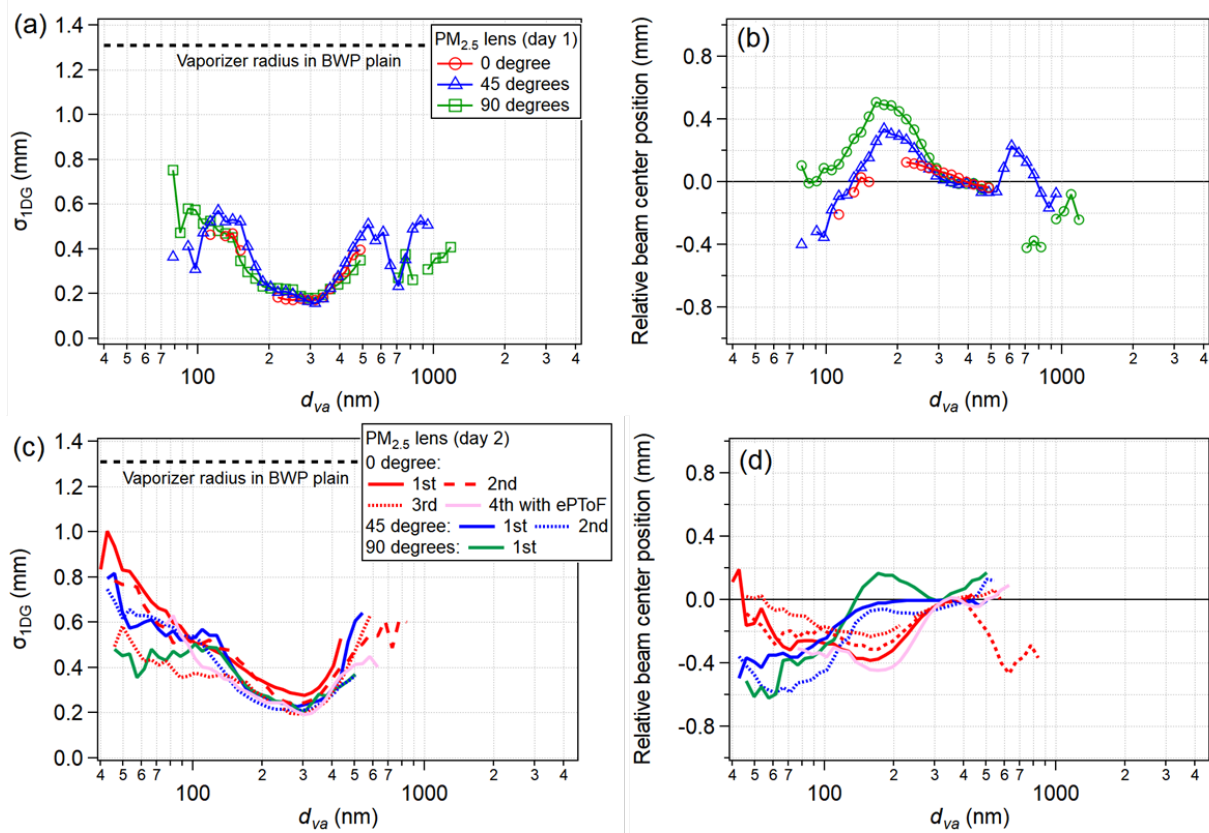

305 **Figure S10.1.** The raw SR-2D-BWP signal attenuations from polydisperse  $\text{NH}_4\text{NO}_3$  with PM<sub>1</sub> lens (1st row), PM<sub>2.5</sub> lens (2nd row), and HPL (3rd row) in 0 (left column) and 90 degrees (right column) rotated axis except for (b) which is 30 degree rotation from X axis. Markers and error bars represent fitted center positions and 1 standard deviation from Gaussian fit at each  $d_{va}$  size bin. Smoothed signal attenuations by Gaussian fitting are shown in Fig 10.

310 **Figure S10.2.** Raw profiles of PM<sub>2.5</sub> lens in 3 different BWP angles on two different days. The 3D nebulizer performance was compromised for unknown reasons for these experiments and the beam profile signal to noise is low above  $\sim 800$  nm  $d_{va}$ . Day-2 profiles were measured after re-installing the lens, hence the orientation of the lens is not the same as Day-1.

315 **Figure S10.3.** Beam center positions and width as a function of  $d_{va}$  shown in Fig. S10.2. Relative center positions are center positions relative to the position at 400 nm  $d_{va}$ . The beam width reached a minimum of around 300 nm  $d_{va}$ .

## S11. PCI comparison

320 **Figure S11.1.** Solid models of the four PCIs deployed with CU-HR-AMS during previous field campaigns, following Guo et al., (2021) Fig S7: (a) PCI-A, (b) PCI-B, (c) PCI-C, and (d) PCI-D. All PCIs consist of a PCI pump port between two critical orifices ( $CO_{up}$  and  $CO_{down}$ ) as well as a custom-designed expansion volume downstream of  $CO_{down}$  to minimize particle losses. Details on expansion volume designs for PCI-A, PCI-B, and PCI-C are discussed in Guo et al. (2021). Another expansion volume was added to PCI-D downstream of  $CO_{up}$  since it significantly reduced particle losses. More operational details on the  
325 four PCIs can be found in Table S11.1.

**Table S11.1.** Comparison of setup and performance of PCIs (and ADLs) utilized for CU-HR-AMS airborne measurements in various field campaigns. The optimal altitude range is the altitude range where  $P_{PCI}$  can be kept constant during flight (assuming ambient  $T = 0^\circ\text{C}$ ). During the ATom-1 campaign, both PCI-B (for the earlier part) and PCI-C (for the later part) were used.

340

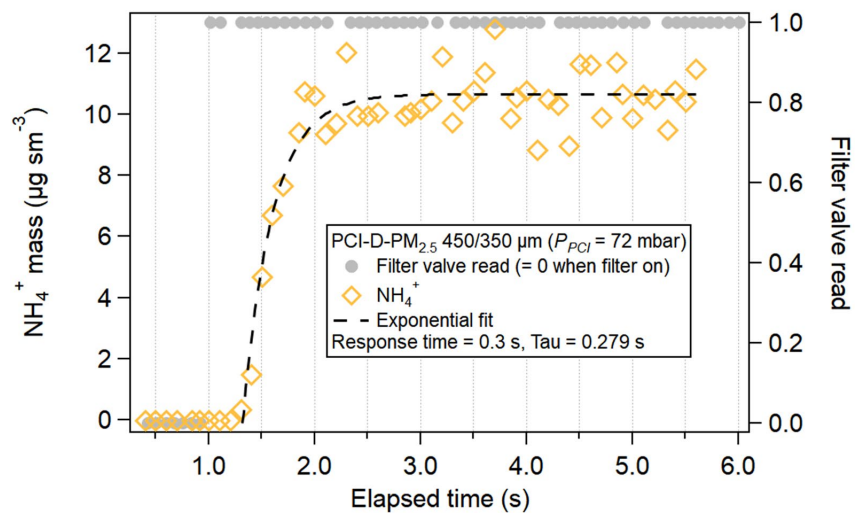

**Figure S11.2.** Transmission efficiency of PCI-D-HPL ( $P_{PCI} = 72$  mbar) in comparison to PCI-D-PM<sub>2.5</sub> at different  $P_{PCI}$ .

345 **Figure S11.3.** Measurable size distribution with three different inlet configurations in the upper troposphere when there was strong Aitken mode aerosols during ATom campaign. Compared to the inlet with PM<sub>1</sub> lens, sampling efficiency of Aitken mode aerosols with PCI-D-PM<sub>2.5</sub> inlet was not significantly compromised. If the transmission efficiency measured by Xu et al. (2017) is applied (below 300 nm) to the inlet, Aitken mode sampling efficiency is significantly compromised.

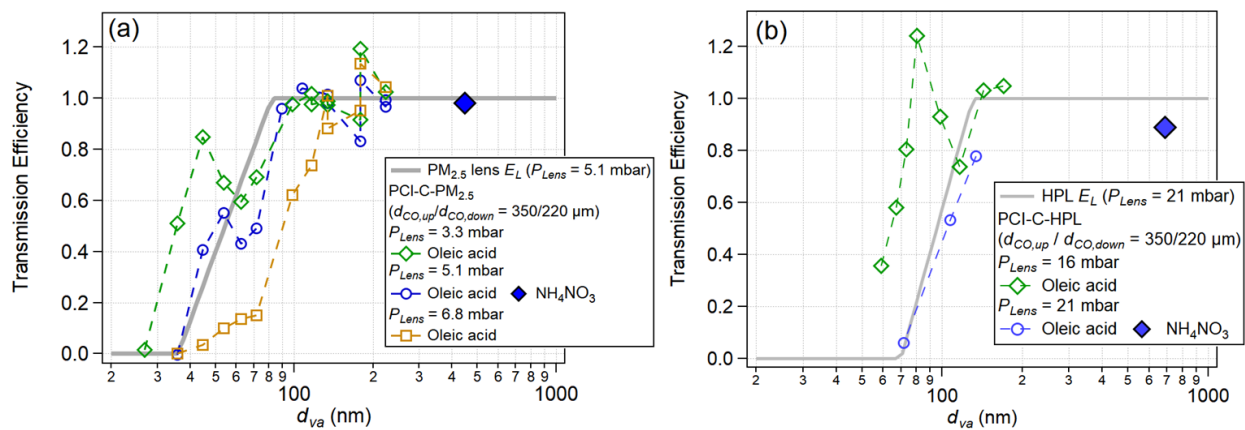

**Figure S12.1.** The residence time (RT) of the PCI design in Bahreini (2008) is long ( $\sim 5$ s) due to a large internal volume. For the PCI-C, the residence time has been improved by reducing both the length and ID and using an improved internal takeoff design, to achieve an internal volume of only  $3.5$  cm<sup>3</sup> (vs.  $\sim 30$  cm<sup>3</sup> in Bahreini et al., 2008) (Guo et al., 2021). In this work, the residence time (from the entrance of PCI ,i.e., CO<sub>up</sub>, to the AMS vaporizer) of PCI-D has been calculated using simple linear plug flow assumptions and experimentally measured using calibration particle puffs (Fig S12.2). RT of PCI-D is 0.2-0.5s depending on the altitude (inlet pressure) which is  $\sim$  half of PCI-C. The shortened residence time was achieved mostly due to the reduced expansion volume and lower PCI pressure.

360 **Figure S12.2.** An example of residence time measurement with  $\text{NH}_4\text{NO}_3$  shown in Fig. S12.1. Both filter valve status and AMS data are acquired at 10 Hz. The tau from exponential fit is the characteristic residence time of aerosol downstream of  $\text{CO}_{\text{up}}$ .

### S13. Effect of $P_{Lens}$ on small particle transmission

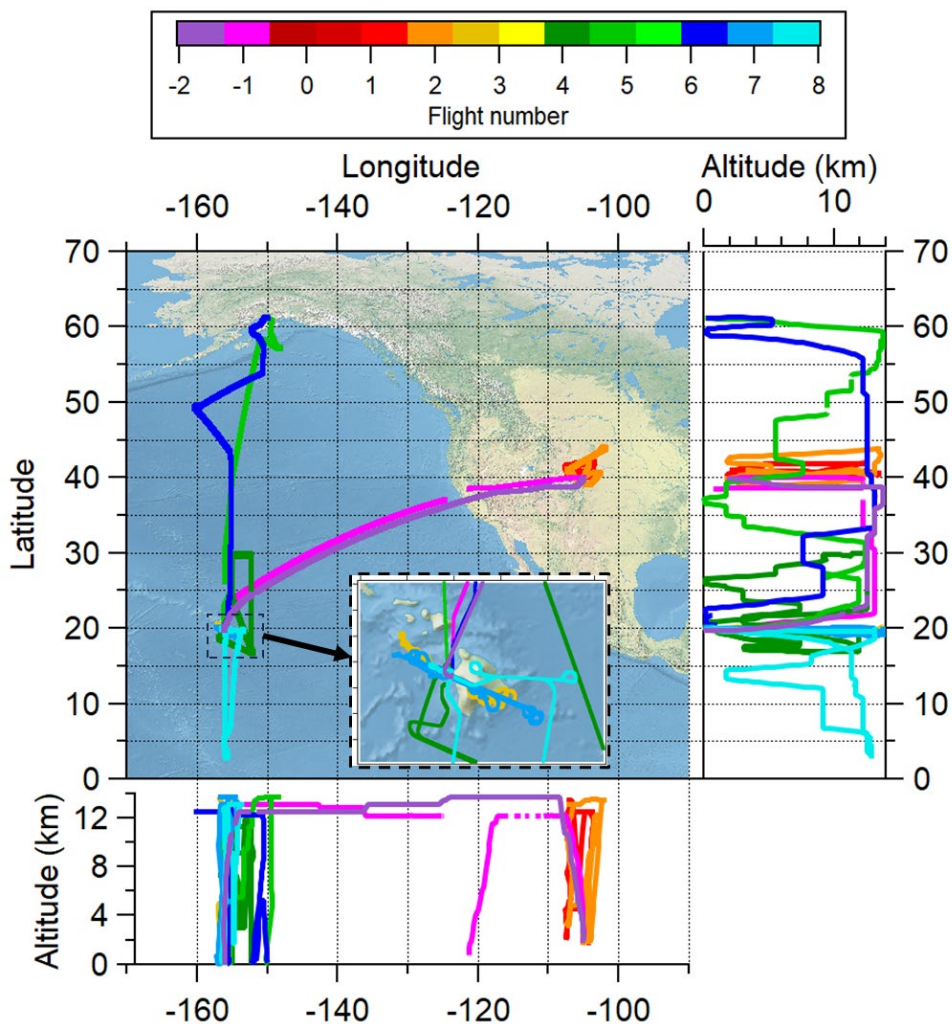

365

**Figure S13.1.** Particle transmission of PM<sub>2.5</sub> lens and HPL was measured at different lens pressures. PCI-C was used to reduce lens pressure.

**Table S14.1.** Location and critical orifice configuration for each flight during TI<sup>3</sup>GER. RF: Research Flight, FF: Ferry Flight between CO and HI.

Flight number	Date	Location	$d_{CO1}/d_{CO2}$ ( $\mu\text{m}$ )
RF01	04/02/2022	CO	450/350
RF02	04/07/2022	CO	450/350
FF01	04/11/2022	CO to HI	450/350
RF03	04/13/2022	HI	450/350
RF04	04/15/2022	HI	450/350
RF05	04/20/2022	HI to AK	450/300
RF06	04/21/2022	AK to HI	450/300
RF07	04/23/2022	HI	450/300
RF08	04/27/2022	HI	450/300
FF02	04/29/2022	HI to CO	450/300

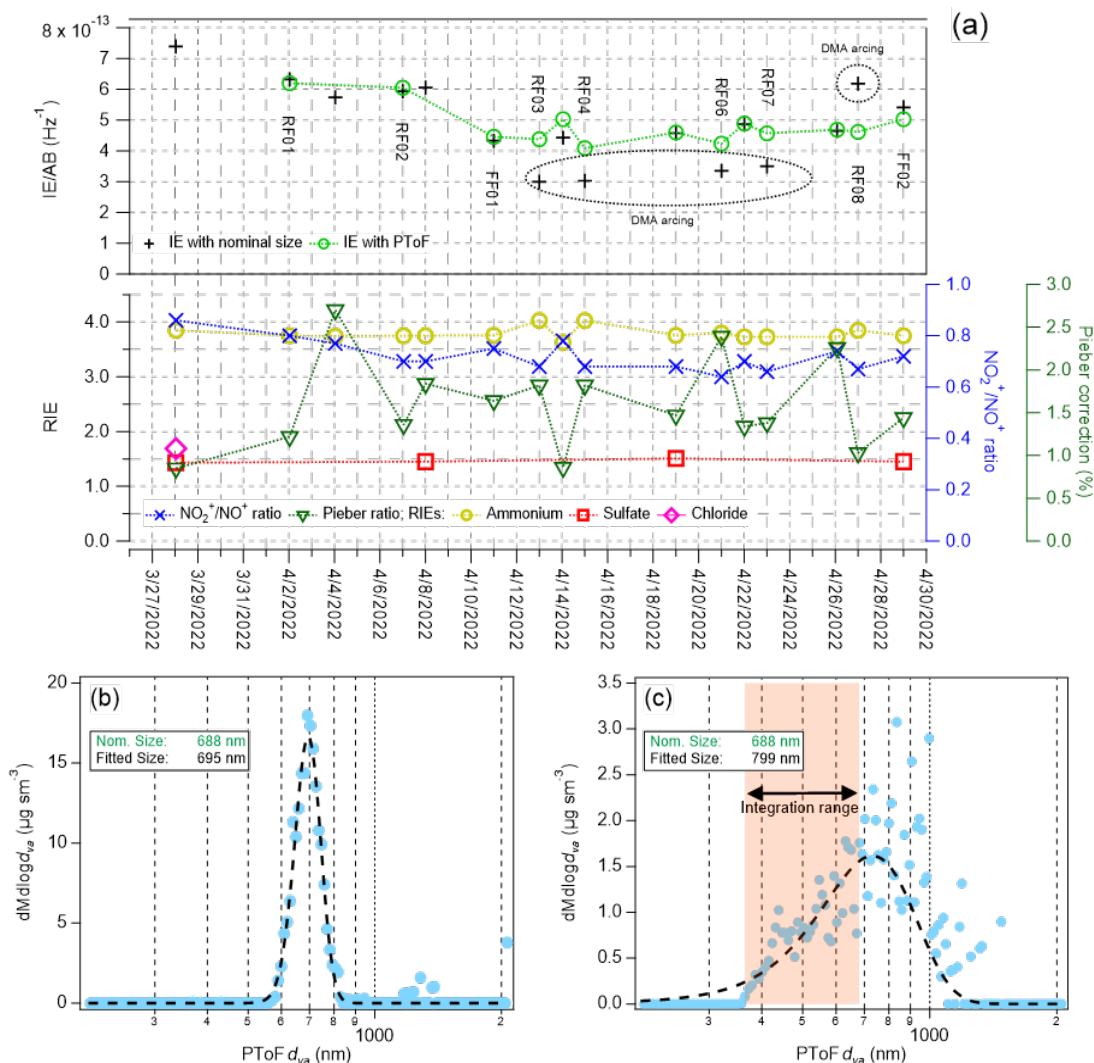

375

**Figure S14.1.** Flight track and altitude during the TP<sup>3</sup>GER campaign. The positive flight numbers are research flight numbers. The negative numbers stand for the ferry flights from CO to HI (FF01, “-1”) and HI to CO (FF02, “-2”), respectively. Note that data were gathered during the ferry flights and were included in the analysis of this study.

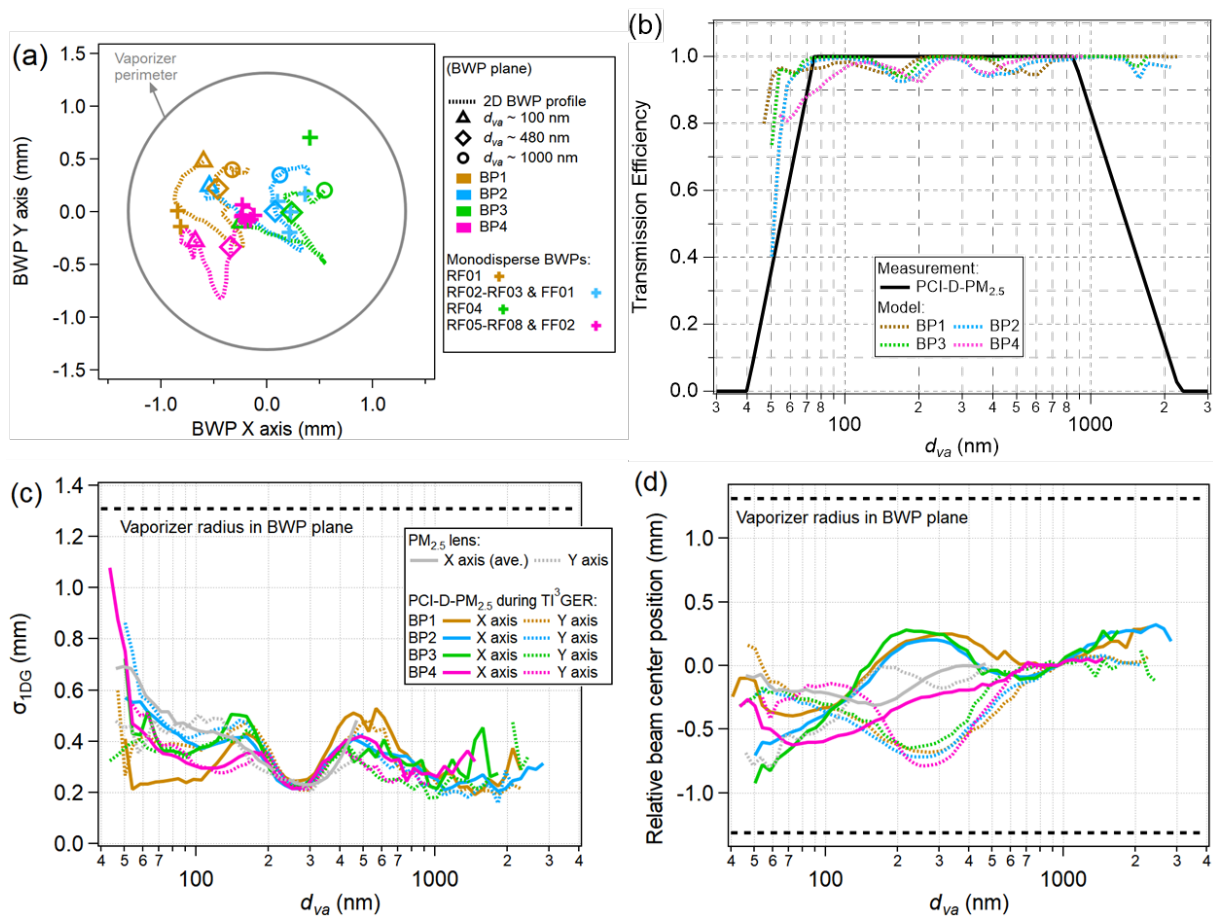

380

## S15. AMS calibration during TI<sup>3</sup>GER

**Figure S15.1.** (a) Ionization efficiency (IE) and relative ionization efficiency (RIE) of major species during the TI<sup>3</sup>GER campaign. The Pieber correction is the amount of  $\text{CO}_2^+$  signal generated by nitrate reaction on the vaporizer (Pieber et al., 2016). For the event trigger (ET) calibrations after flights, the DMA was placed outside the airplane and the particles were delivered to the AMS inside the airplane. In HI (after RF03-RF08), the DMA output was not very stable showing signs of arcing as shown in (c), potentially due to nitrate evaporation in the hot DMA. When the output of DMA was not monodisperse, IE was estimated based on the particle sizes measured by PToF during ET cycles (green circles). The particle size range where the distribution is reasonable without too much noise was selected. Particles outside of the size range were excluded from the IE analysis. When the DMA output was monodisperse, as shown in (b), the mobility diameter was used to calculate the volume of calibration aerosol (black cross in (a)). In those cases, both methods yield comparable IE.

## S16. BWP results during the TI<sup>3</sup>GER campaign

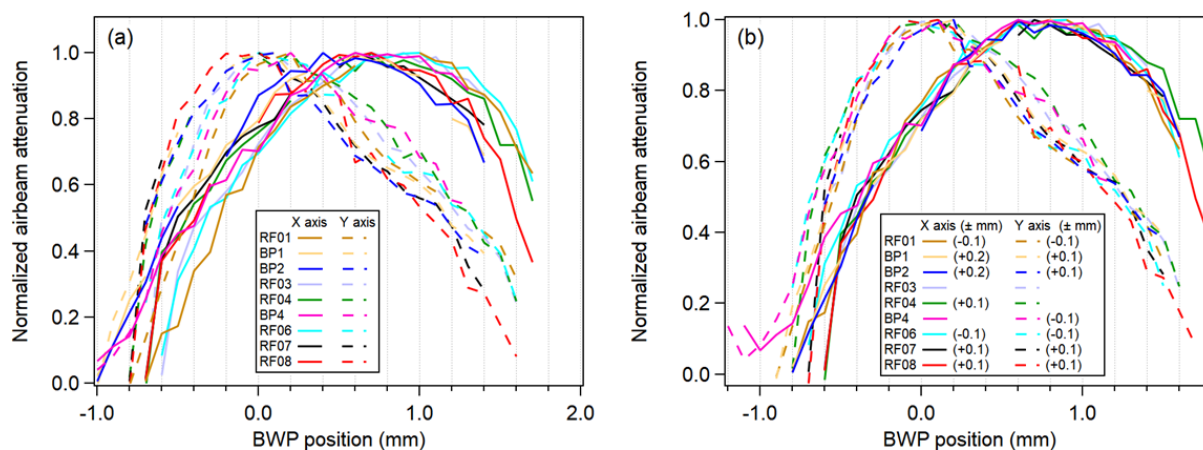

395 **Figure S16.1.** (a) Compilation of beam center positions as a function of  $d_{va}$  measured from 2D-SR-BWP analysis during TI<sup>3</sup>GER campaign (dashed lines). The gray circle is the vaporizer perimeter at the BWP plane. The triangle, diamond and circle markers represent beam center positions of  $\sim 100$ ,  $\sim 480$ , and  $\sim 1000$  nm  $d_{va}$ , respectively, from each beam profile from 2D-SR-BWP (BP1-BP4). Cross markers are beam positions of 2D-BWP with monodisperse aerosols after flights. After performing each 2D-SR-BWP, the inlet system was secured with screws which can move the lens during the process. In order to obtain the beam profiles after securing the lens, the profiles were moved to match with the monodisperse 2D-BWP after flights (Fig. 16). These four 2D-SR-BWP measurements were performed on 4/4 (between RF01 and RF02), 4/5 (between RF01 and RF02), 4/14 (between RF03 and RF04), and 4/16/2022 (between RF04 and RF05), respectively. After BP1, PCI was cleaned and re-installed. BP2 was measured after lens adjustment toward the center. BP3 was measured just for check without changes in the inlet. However, the lens seemed to be moved during inlet lockdown after BP3 or during RF04 for some reason. BP4 was measured after switching CO<sub>down</sub> from 350  $\mu\text{m}$  to 300  $\mu\text{m}$ . Also, CO<sub>up</sub> was cleaned after BP4. (b) Modeled particle transmission (markers) from the four 2D-SR-BWPs and the measured TE (solid line) of PCI-D-PM<sub>2.5</sub> with 450/350

400

405

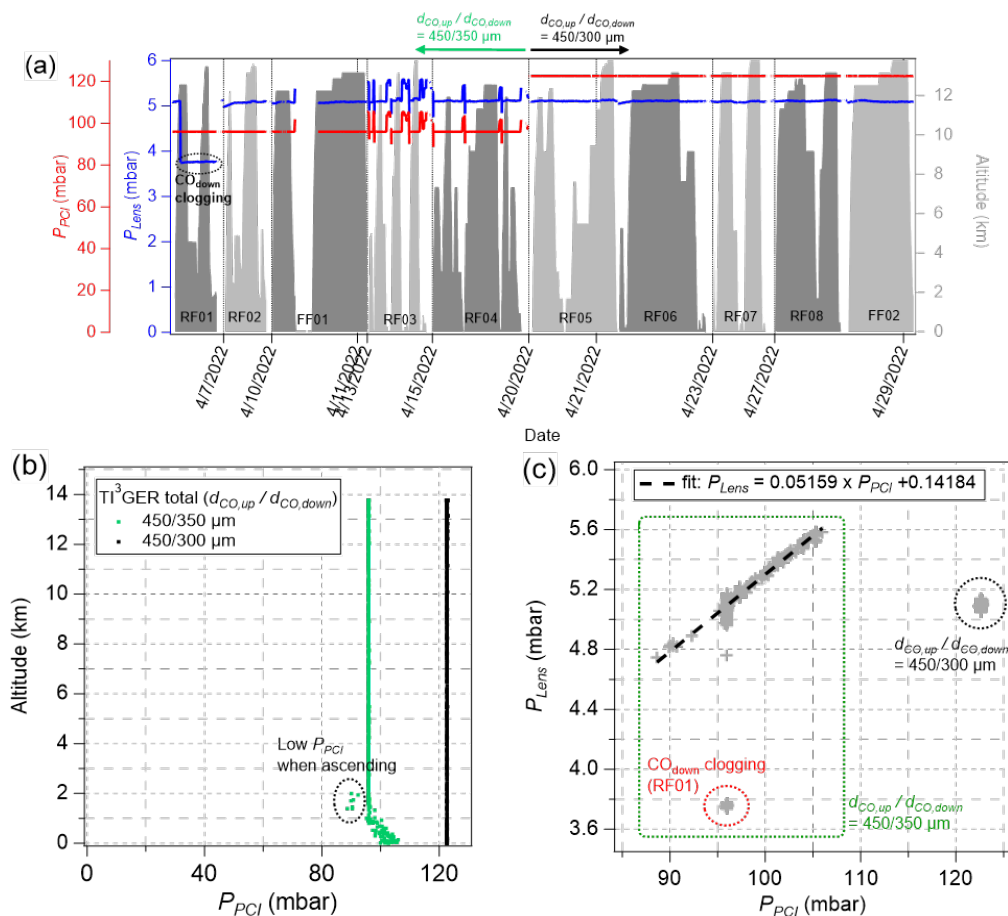

$\mu\text{m}$  ( $d_{CO,up} / d_{CO,down}$ ). These TEs are before correcting the profiles to match with monodisperse 2D-BWPs. (c)  $\sigma_{1DG}$  and (d) relative beam center position of BP1-BP4 and the  $\text{PM}_{2.5}$  lens in the X and Y axes as a function of  $d_{va}$ . The results from the  $\text{PM}_{2.5}$  lens are from Fig. S10.3c-d. There were several reconfigurations of the AMS inlet since the experiments in Fig. S10.3c-d, thus the rotational orientation of the  $\text{PM}_{2.5}$  lens in those experiments was different from the TI<sup>3</sup>GER configuration, and thus, X and Y axes do not necessarily represent the same axial beam information between the two cases. Regardless, (c) shows that beam width in two different axes are similar (i.e., beam cross section is circular) and the addition of PCI-D does not significantly change the beam width. In (d), the  $\text{PM}_{2.5}$  lens in the Y axis shows a similar degree of shift in beam center position across  $d_{va}$  than PCI-D- $\text{PM}_{2.5}$  while the shift in the X axis is less variable than that of PCI-D- $\text{PM}_{2.5}$ . However, since the  $\text{PM}_{2.5}$  lens was not installed in the same rotational orientation, it is not appropriate to conclude that the use of PCI-D magnifies the shifts in beam center positions.

**Figure S16.2.** (a) Air beam (AB) signal with the default offset correction (-0.5 mm in X axis, -0.6 mm in Y axis). (b) The same graph with additional corrections (within  $\pm 0.2$  mm) for better alignment in the air beam profile. Careful inspection of the BWP AB recorded at high resolution for many runs revealed what appears to be inconsistent zeroing of the BWP in the control software, with a maximum variability of 0.2 mm. Hence all data shown here has been corrected using the BWP AB as datum.

425

## S17. Aircraft inlet logs during the TI<sup>3</sup>GER campaign

- 430 **Figure S17.1.** (a) Time series of  $P_{PCI}$ ,  $P_{Lens}$ , and altitude. The CO<sub>down</sub> clogging (RF01) occurred ~ 40 minutes after the flight and was resolved during landing (before IE calibration & 1D-BWPs). The CO<sub>up</sub>/CO<sub>down</sub> configuration of PCI-D was 450/350  $\mu\text{m}$  ( $P_{PCI} = 96$  mbar) during RF01-RF04 & FF01 (ferry flight from Colorado to Hawaii) and 450/300  $\mu\text{m}$  ( $P_{PCI} = 122.6$  mbar) for RF05-RF08 & FF02 (ferry flight from Hawaii to Colorado). The PCI-D of both critical orifice configurations successfully maintained the constant  $P_{PCI}$  at high altitudes during the campaign (maximum ~ 13.8 km). The 450/350  $\mu\text{m}$  configuration
- 435 failed to maintain the constant  $P_{PCI}$  below 1.6 km altitude due to the pressure drop at the PCI flowmeter and the limitation in pumping capacity of the PCI pump. This increased the  $P_{Lens}$  up to 5.7 mbar at sea level. The increased  $P_{Lens}$  (~ 10%) might have affected the  $d_{va,50,low}$  negatively but not significantly (Fig. S13.1). (b) Altitude vs.  $P_{PCI}$  for both critical orifice configurations. In the 450/350  $\mu\text{m}$  configuration, the PCI pumping control did not work smoothly when G-V was ascending above 1 km altitude, resulting in lower  $P_{PCI}$  than the set value. (c)  $P_{Lens}$  vs.  $P_{PCI}$ . In 450/350  $\mu\text{m}$  configuration,  $P_{Lens}$  responded
- 440 linearly to the higher (below 1.6 km altitude) and lower (ascending above 1 km altitude)  $P_{PCI}$  than the set  $P_{PCI}$ .

**Figure S17.2.** The optimal operation altitude ranges in Fig. 15d were calculated as an altitude at which ambient pressure is equal to  $P_{PCI}$  without considering the pressure gain due to ram pressure. The measured pressure gain due to the ram pressure during the flight as a function of ambient pressure is shown here, following  $\text{Pressure gain (\%)} = 100 \times (\text{sampling line pressure downstream of HIMIL} - \text{ambient static pressure}) / \text{ambient static pressure}$ . This means that with CU-AMS inlet configuration during TI<sup>3</sup>GER on G-V, the actual optimal altitude range is ~ 1 km higher.

### S18. Particle transmission through sampling lines during TP<sup>3</sup>GER

450 **Figure S18.1.** Calculated aerosol transmission through (a) the plumbing upstream of PCI and (b) the whole inlet (including  
PCI-D-PM<sub>2.5</sub>) as a function of altitude. In addition to the particle losses in PCI and ADL, particles are lost in the sampling  
lines downstream of the tip of the secondary diffuser, while there are small particle concentration effects at the takeoffs. Losses  
in the HIMIL (before the secondary diffuser) were not included. Calculations were performed with a custom fluid-dynamics  
equation package, as described in Guo et al. (2021) and Bourgeois et al. (2022).

## S20. Post-campaign characterization of air slowdown inside the HIAPER Modular Inlet (HIMIL)

470 HIAPER Modular Inlet (HIMIL) (Fig. 2 and Fig. S20.1) is a flow-through inlet facing flight direction with a diffusing nozzle  
upstream and a converging nozzle downstream which is broadly used for in-situ sampling on research aircraft (Stith et al.,  
2009) They are typically flown with a choice of two spacers, a standard one (19 cm above the fuselage) and a tall one (29.5  
cm above the fuselage), the one used for both the TI3GER AMS sampling and the characterization here is the latter one, with  
less chance of boundary layer contamination. The HIMIL is used both for gas-phase and particle-phase species, with the gas-  
475 phase version using a larger nozzle ID ( $\frac{1}{2}$ " vs  $\frac{3}{8}$ "") and an active choke on the exhaust; these measurements focus on the original  
version optimized for aerosols. As a sharp-edged diffuser inlet, the HIMIL that could potentially exhibit directional losses for  
larger particles (Baumgardner and Huebert, 1993). During the Pacific Dust Experiment (PACDEX) four HIMILs were  
deployed. The calculated particle passing efficiencies of approximately 94 to 110% for particles 1  $\mu\text{m}$  diameter and smaller,  
over the range of typical G-V sampling altitudes (sea level to 12 km) and airspeeds (120–260  $\text{m s}^{-1}$ ) (Stith et al., 2009).

480 Several cross-comparisons of aerosol measurements between HIMIL and different types of inlets such as Blunt-body  
Aerosol Sampler (Moharreri et al., 2013), Submicron Aerosol Inlet (Ortega et al., 2019), and NASA Langley Aerosol Research  
Group inlet (Guo et al., 2021) have been reported. Guo et al. (2021) showed that using a completely different inlet with proven  
supermicron transmission (McNaughton et al., 2007; Brock et al., 2019) while maintaining the same conditions in the  
downstream plumbing, had no appreciable impact on the intercomparisons with other optical aerosol instruments during back-  
485 to-back inlet switches. However, to the best of our knowledge, there has been no experimental characterization of the HIMIL  
inlet itself. Since quantitative, unbiased sampling thru the secondary diffuser using for AMS operation depends on roughly  
matching the flow speed in the HIMIL and the secondary diffuser, the air slowdown factor of the HIMIL (or the air speed  
inside HIMIL) at each altitude needs to be known. An estimated slowdown of ambient air from plane airspeed by a factor of  
3-4 inside the diffuser has been suggested (D. Rogers, NCAR, personal communication) while assuming laminar flow  
490 expansion in the diffuser would suggest a slowdown factor as high as 11.75.

For TI<sup>3</sup>GER, the flow is then sampled into a straight, sharp-edged 3.8 mm internal diameter (ID) stainless steel tube  
pointing in the flow direction (called here the "secondary diffuser") (Guo et al., 2021). The small particle losses through the  
HIMIL and secondary diffuser are negligible due to fast residence time. Large particle ( $\sim 1 \mu\text{m}$  diameter) transmission can be  
affected by the particle transmission through the tip of the HIMIL as the air slows down (passing efficiency),  
495 over/undersampling at the tip of the secondary diffuser depending on the flowrate at the secondary diffuser, and the impaction  
loss in the particle sampling line downstream of the secondary diffuser. The particle impaction at the 90-degree bend at the  
secondary diffuser inside HIMIL (Fig. S20.1) is the largest loss, especially for larger particles. Thus, reducing the flow rate at  
the secondary diffuser, while maintaining near isokinetic sampling at the secondary diffuser is the key to enhancing large  
particle transmission.

500 The objective of the characterization in this section is to evaluate the flow velocity along the centerpiece of the HIMIL  
(where the secondary inlet is normally placed), in order a) to determine to what extent flow speeds are slowed down in the

HIMIL compared to the ambient flow speed and b) to evaluate the symmetry of the flow profile and the likelihood of flow separation (or “jetting”). In this section, we present the airspeed measurements inside HIMIL as a function of height and its dependency on the angle of attack at the U.S. Air Force Academy (USAFA). Airspeed was calculated based on the measured ram pressure (or stagnation pressure,  $P_t$ ) from a (ID: 1.34 mm, OD: 1/16”) and static pressure ( $P_s$ ) measured at the HIMIL inside wall, following Eq. S20.1 which is valid for Mach numbers  $< 0.3$  (measured flow velocities inside the HIMIL were  $< 0.1$  Mach).

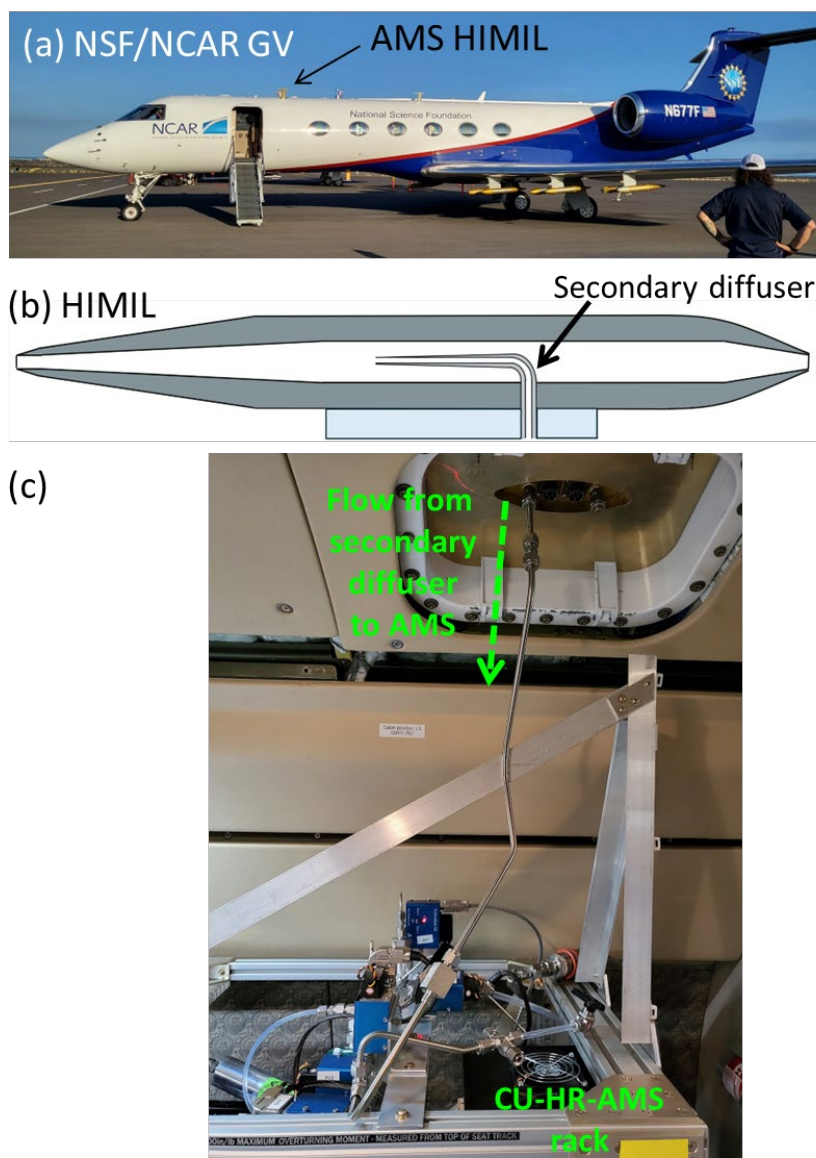

$$u = \sqrt{\frac{2(P_t - P_s)}{\rho_{air}}}, \quad (\text{Eq. S20.1})$$

where  $u$  is the speed of air and  $\rho_{air}$  is the density of air after being corrected by temperature and pressure. The air speed inside HIMIL over a range of external air speeds was measured at three pitot tube locations (referred to as front, middle, and back positions; Fig. S20.2a).

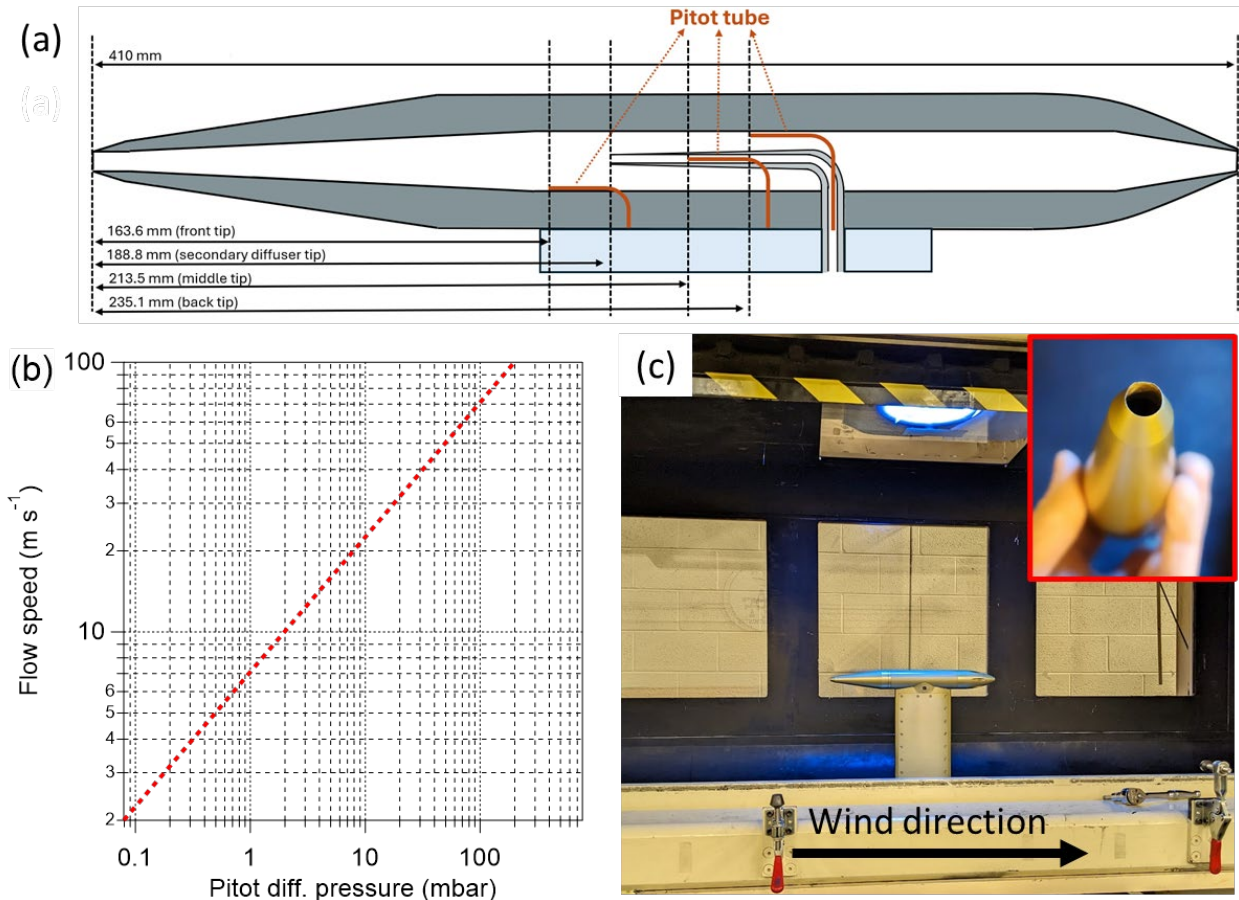

During the wind tunnel experiments at USAFA, a pressure sensor (KMPS-4-64-XX-Y series, Kulite Inc.), acquiring at 250 Hz sample rate, was used for differential pressure measurements. The full vertical profiles of air speed inside the HIMIL over a range of wind tunnel air speeds were measured at the front, middle, and back locations. Four wind speeds ( $100 \text{ m s}^{-1}$ ,  $125 \text{ m s}^{-1}$ ,  $150 \text{ m s}^{-1}$ , and  $180 \text{ m s}^{-1}$ ) were chosen for the vertical profile measurements to cover the range of typical airspeeds at the HIMIL tip from various aircraft research platforms (NSF GV, NSF C130, NASA DC-8) while probing the lower 5 km of the atmosphere. Given the limitations of the tunnel (ambient T and P, max Mach number of 0.55), these experiments do not cover conditions in the upper troposphere and stratosphere (Fig. S20.3). Before each vertical profile measurement, the pitot tube was placed at the center height measuring the HIMIL internal air speed as the wind tunnel air speed increase by  $\sim 10 \text{ m s}^{-1}$  step (“speed run”). After the wind tunnel air speed reached the maximum speed ( $180 \text{ m s}^{-1}$ ), the wind tunnel air speed slowed down to the four selected speeds and the pitot tube height measured the airspeed profile at each speed. Measurement at each speed was averaged for 5-10 s. Up to  $180 \text{ m s}^{-1}$  (Mach 0.52), flow separation (or “jetting”) was not observed, although the airspeed vertical profile was asymmetric in the front position (Fig. S20.4a) (this could partially be related to a slight deformation to the front cone during the experiments, see Fig. 20.2c). The symmetry of the vertical profile is achieved as the air travels further back (Fig. S20.4b-c). The “speed run” data at the three pitot positions shows that the air speed slowdown ratio of the HIMIL is about a factor of 7.4 (Fig. S20.4d) at the position of the tip of the secondary diffuser. The air speed decreased towards the back of the HIMIL by  $\sim 35\%$ , almost approaching the full expansion value. The reason behind the airspeed slowdown in the back side of HIMIL could not be conclusively assessed. On the other hand, the static pressure measurements on the front, middle, and back positions were nearly identical indicating the air speed would have been similar among the three locations. This discrepancy will be investigated in future studies. Leaks around HIMIL component fittings were not found. The air speed inside HIMIL decreased as the pitch angle deviated from 0 degree, up to  $\sim 15\%$  (at +7 degrees; Fig. S20.5).

During the TI<sup>3</sup>GER campaign, the air speed at the tip of the secondary diffuser (determined by the flow rate) was faster than the air speed around the tip (estimated by the wind tunnel data, grey marker, Fig. S20.6). From the extrapolation of

535 the wind tunnel data, this indicates that there may have been a minor degree of undersampling of particles near  $\sim 1 \mu\text{m}$  volume  
equivalent diameter ( $d_{ve}$ ) by the secondary diffuser, although the flow field during actual flight conditions (low temperature  
and pressure) could deviate from the extrapolation. However, such undersampling is minor and the contribution of particles  
with  $\sim 1 \mu\text{m}$   $d_{ve}$  ( $\sim 1.6 \mu\text{m}$   $d_{va}$ ) to mass in accumulation mode aerosols is a small fraction (Fig. 17). Thus, this effect does not  
540 meaningfully affect aerosol quantification compared to the particle losses in the sampling line downstream of the secondary  
diffuser. In future campaigns, the sampling flow rate from the secondary diffuser can be adjusted to minimize the particle  
losses in the sampling downstream of the secondary diffuser while achieving near isokinetic sampling.

545 **Figure S20.1.** (a) Location of HIMIL for CU-HR-AMS on GV. (b) Cross section of HIMIL and the location of the secondary diffuser. (c) Aerosol sampling line downstream of the secondary diffuser.

550 **Figure S20.2.** (a) Locations of three pitot tube positions (front, middle, and back) inside HIMIL. When conducting ram pressure measurement at one pitot tube position, another port is used for static pressure measurement and the other port is blocked. (b) The relationship between the measured differential pitot pressure and the flow speed (Eq. S20.1). (c) HIMIL installed inside the wind tunnel at the U.S. Air Force Academy. The inset picture in red box shows the slightly deformed front cone of the HIMIL tested and deployed during the TI<sup>3</sup>GER.

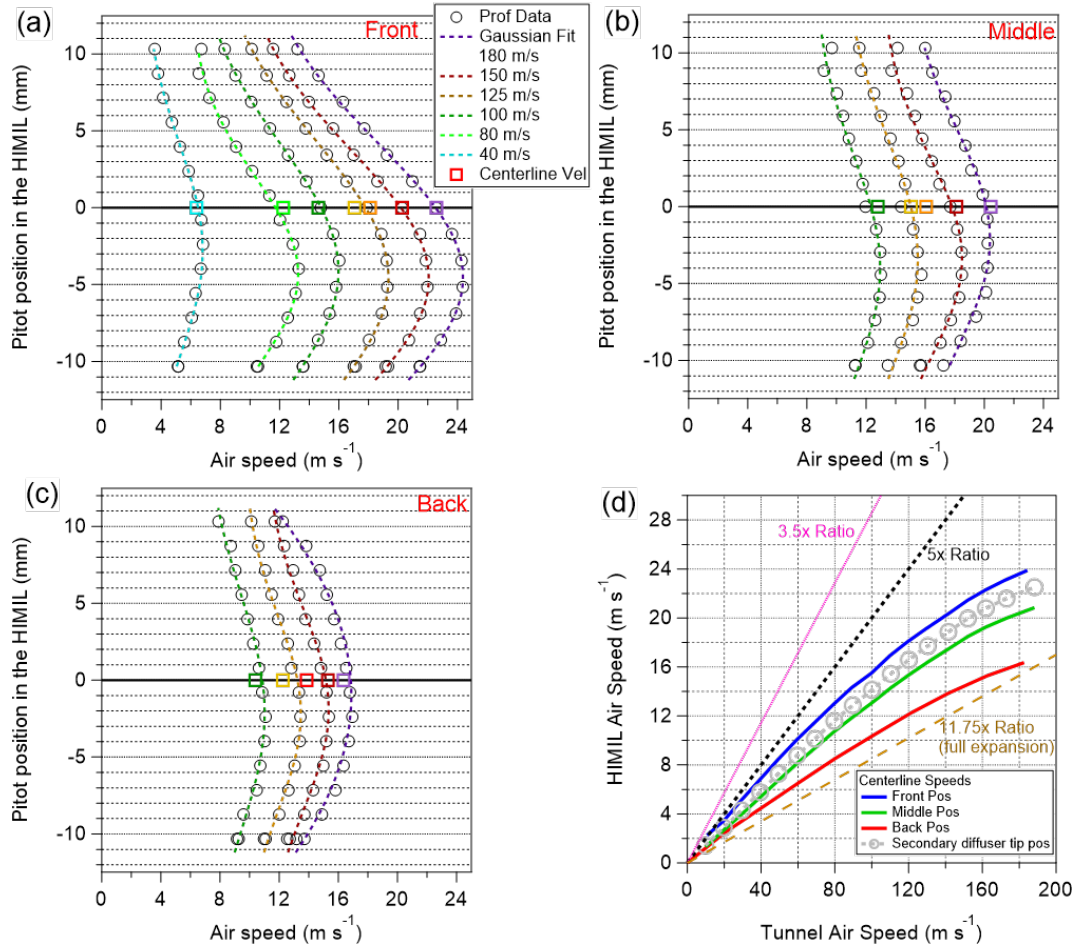

555

560 **Figure S20.3.** Reynolds number at the HIMIL tip vs Mach number for the polar of different aircraft platforms compared to  
 the range of conditions accessible by the wind tunnel. The wind tunnel condition overlap with the inlet conditions of research  
 aircraft at lower altitudes (below ~5 km). This suggests that the HIMIL experiment with wind tunnel is more representative of  
 low altitude condition and, at higher altitude, the wind tunnel result on air speed slowdown could deviate from research flight  
 conditions.

565

570

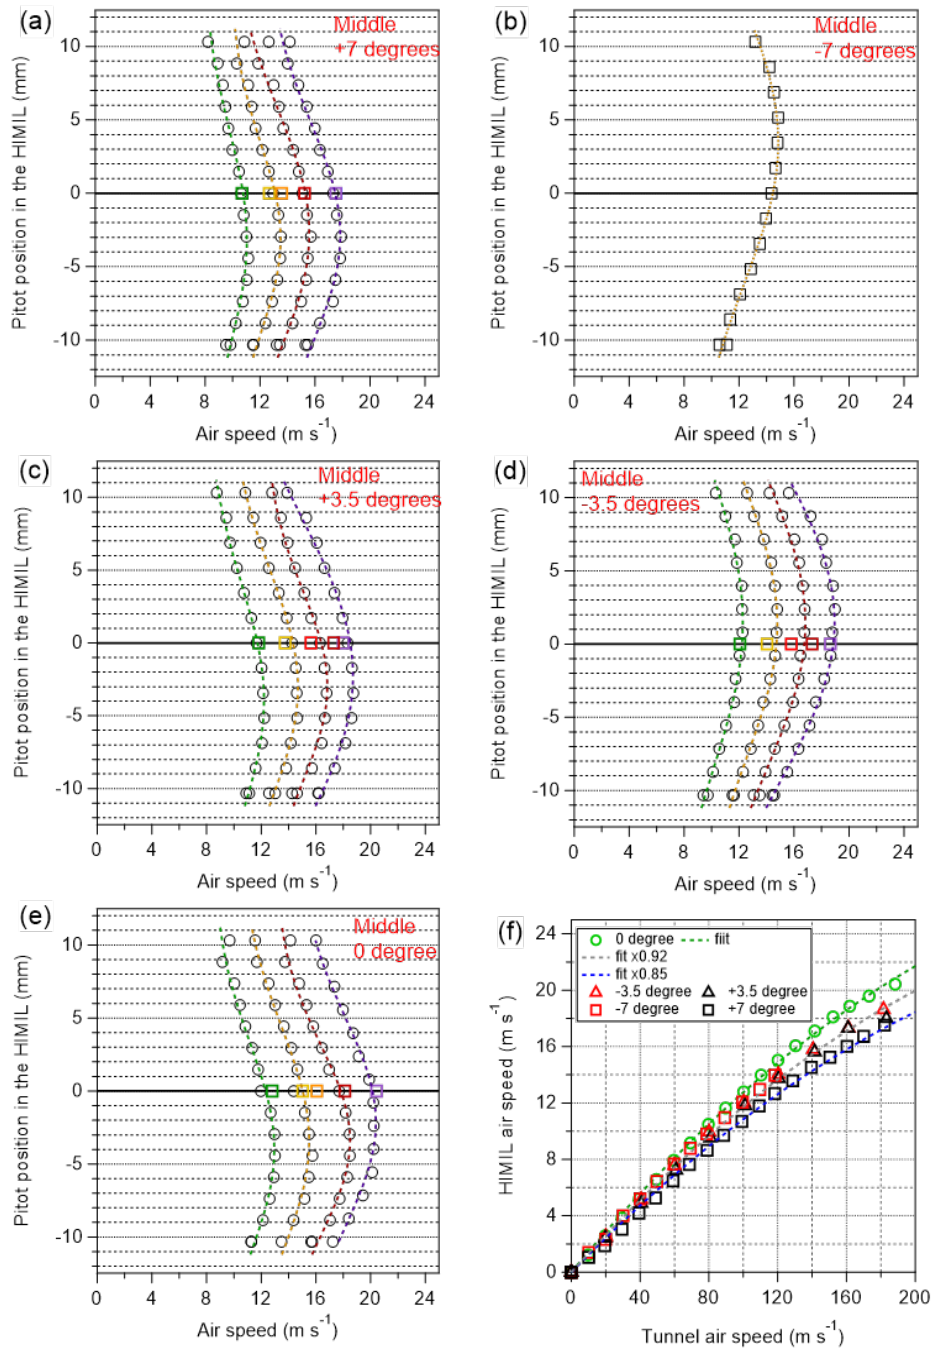

575

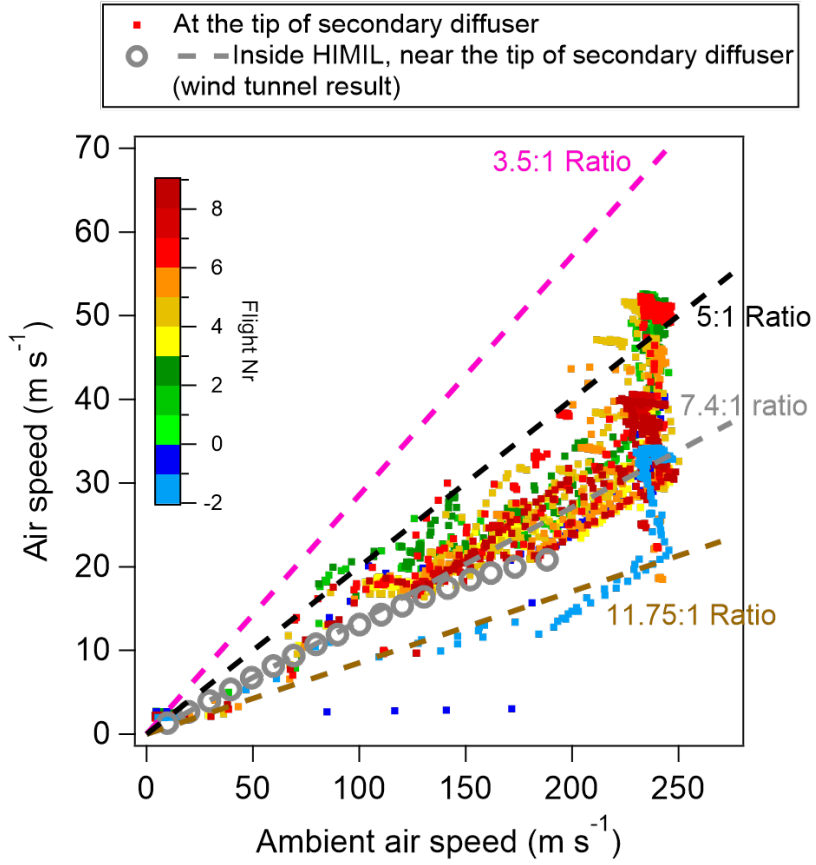

**Figure S20.4.** The wind tunnel measurement of air speed vertical profile inside HIMIL at (a) front, (b) middle, (c) back positions. Centerline velocity is air speed measured during the continuous “speed run” cycle at the same tunnel air speed where profile measurements were conducted. The fact that the air speed from profiles and “speed run” agree indicates that the air speed measurement is reproducible. (d) HIMIL air speed vs tunnel air speed at the front, middle, and back pitot positions at the center height. HIMIL air speed decreased toward the back side of HIMIL. Gray markers are the estimated HIMIL air speed at the location of the tip of the secondary diffuser.

580

**Figure S20.5.** The wind tunnel measurement of airspeed profile inside HIMIL at different pitch angles for the middle pitot position. Profiles of 0, +3.5, +7.5 degrees are skewed towards the bottom by similar amounts. The +7 deg pitch is noticeably slower than 0 deg (by ~ 15 %). -7.5 deg on the other hand looks like expected. The overall effect on air speed, especially for realistic pitch angles (e.g. -3.5 to +3.5 deg) is modest (within ~ 8 %).

590 **Figure S20.6.** The calculated air intake speed at the tip of the secondary diffuser during the TI<sup>3</sup>GER campaign and the extrapolated air speed inside the HIMIL at the location of the tip of the secondary diffuser from the wind tunnel experiment.
